

This is a digital copy of a book that was preserved for generations on library shelves before it was carefully scanned by Google as part of a project to make the world's books discoverable online.

It has survived long enough for the copyright to expire and the book to enter the public domain. A public domain book is one that was never subject to copyright or whose legal copyright term has expired. Whether a book is in the public domain may vary country to country. Public domain books are our gateways to the past, representing a wealth of history, culture and knowledge that's often difficult to discover.

Marks, notations and other marginalia present in the original volume will appear in this file - a reminder of this book's long journey from the publisher to a library and finally to you.

Usage guidelines

Google is proud to partner with libraries to digitize public domain materials and make them widely accessible. Public domain books belong to the public and we are merely their custodians. Nevertheless, this work is expensive, so in order to keep providing this resource, we have taken steps to prevent abuse by commercial parties, including placing technical restrictions on automated querying.

We also ask that you:

- + *Make non-commercial use of the files* We designed Google Book Search for use by individuals, and we request that you use these files for personal, non-commercial purposes.
- + *Refrain from automated querying* Do not send automated queries of any sort to Google's system: If you are conducting research on machine translation, optical character recognition or other areas where access to a large amount of text is helpful, please contact us. We encourage the use of public domain materials for these purposes and may be able to help.
- + *Maintain attribution* The Google "watermark" you see on each file is essential for informing people about this project and helping them find additional materials through Google Book Search. Please do not remove it.
- + *Keep it legal* Whatever your use, remember that you are responsible for ensuring that what you are doing is legal. Do not assume that just because we believe a book is in the public domain for users in the United States, that the work is also in the public domain for users in other countries. Whether a book is still in copyright varies from country to country, and we can't offer guidance on whether any specific use of any specific book is allowed. Please do not assume that a book's appearance in Google Book Search means it can be used in any manner anywhere in the world. Copyright infringement liability can be quite severe.

About Google Book Search

Google's mission is to organize the world's information and to make it universally accessible and useful. Google Book Search helps readers discover the world's books while helping authors and publishers reach new audiences. You can search through the full text of this book on the web at <http://books.google.com/>

M.DCCC.LVI.

1856

L.

LABDANUM or **LADANUM**, is an unctuous resin, of an agreeable odor, found besmearing the leaves and twigs of the *cythus creticus*, a plant which grows in the island of Candia, and in Syria. It is naturally a dark-brown soft substance, but it hardens on keeping. Its specific gravity is 1.186. It has a bitter taste. Its chief use is in surgery for making plasters.

LABOR-SAVING MACHINES IN THE GREAT EXHIBITION.—*Printing and numbering Cards*.—It will be remembered, that in the early days of railway travelling, the ticket system then in vogue at the various stations was a positive nuisance; as every ticket before it was delivered to a passenger had to be stamped, and torn out of a book,—thus causing the loss of considerable time to travellers when many passengers were congregated. But this was the least evil; for the railway directors had little or no check upon their servants, and therefrom resulted many ingenious and successful frauds. The first to remedy this was Mr. Edmondson, who constructed an ingenious apparatus for printing the tickets with consecutive numbers, and also dating the same. This gave great facilities for checking the accounts of the station clerks; but owing to the imperfect manner of inking, consequent on the construction of the apparatus, the friction to which the tickets were exposed, before they were delivered up, in a great measure obliterated the printing, and occasionally rendered them quite illegible. By Messrs. Church and Goddard's machine for printing, numbering, cutting, counting, and packing railway tickets, this difficulty also is removed, and great speed is attained in manufacturing the tickets, as the several operations which we have enumerated are simultaneously performed. Pasteboard cut into strips by means of rollers, as above explained, is fed into the machine, by being laid in a trough, and brought under the prongs of a fork (working with an intermitting movement), which pushes the strips successively forward between the first pair of a series of guide or carrying rollers. There are four pairs of rollers, placed so as to conduct the strip through the machine in a horizontal line; and an intermittent movement is given them for the purpose of carrying the strips forward a short distance at intervals. The standards of the machine carry, at the top, a block, termed the "platten," as it acts the part of the press head in the common printing machine,—portions of it projecting downwards between the upper rollers of the first and second, and second and third, pairs of carrying rollers, nearly to the horizontal plane, in which the pasteboard lies, so as to sustain it at those points while it receives the pressure of the printing types and numbering discs, hereafter referred to. The types to designate the nature of the ticket, as "Birmingham, First class," are secured in a "chase," upon a metal plate or table, which also carries the numbering discs for imprinting the figures upon the cards; and the table by a cam action is alternately raised, to bring the types and numbering discs in contact with the pasteboard, and then lowered into a suitable position to admit of an inking roller moving over the types and numbering discs, and applying ink thereto. The table likewise carries at one end a knife, which acts in conjunction with a knife-edge projecting downwards from the fixed head of the machine, and thereby gives the cross cut to the strips between the third and fourth pairs of carrying rollers,—thus severing each into a given number of tickets. The strip of pasteboard which is fed into the machine stops on arriving at the second pair of carrying rollers; and, on the ascent of the printing-table, the types print on that portion which is between the first and second pairs of rollers. The strip then passes on to the third pair of rollers, where it stops; and, on the table again ascending, the numbering discs imprint the proper number upon the pasteboard between the second and third pairs; the type, in the meanwhile, printing what is to be the next following ticket. On the next ascent of the table, the strip has advanced to the fourth pair of rollers; and the knives being now brought into contact, the printed and numbered portion of the strip is severed. The now completed ticket is lastly delivered by the fourth pair of rollers into a hollow guide piece, and conducted to a box below, provided with a piston, which, to facilitate the packing of the tickets in the box, can be adjusted to any height to receive the tickets as they fall. To avoid the necessity of having to count the tickets after they are taken from the receiving box, a counting apparatus, connected with the working parts of the machine, is made to strike a bell on the completion of every hundred or more tickets, so as to warn the attendant to remove them from the box. The inking apparatus is assimilated in character to self-acting inkers in ordinary printing presses; and the numbering discs are worked in a manner very similar to those for paging books.

A simple arrangement of apparatus for printing and numbering cards was exhibited by Messrs. Harrild & Sons. The types are fixed in a metal frame, which also carries the numbering discs. This frame is mounted on a rocking shaft, and is furnished with a

handle, whereby it is rooked to bring down the types and discs upon the card, to produce the impression. When the frame is raised again, the units disc is moved forward one figure, and the types are inked by a small roller, which takes its supply of ink from an inking table, that forms the top of the frame. This is a useful description of machine; but the specimen in the Exhibition does not appear to have been properly adjusted, as the figures of the numbering discs have a tendency to cut through the card.

M. Baranowski, of Paris, exhibits a machine for printing and numbering tickets, and also indicating the number printed. The types and numbering discs are carried by a horizontal rotating shaft, upon which, near each end thereof, is a metal disc; and upon the periphery of these discs, a metal frame is affixed, which carries the types and numbering discs, and corresponds in curvature with the edge of the discs. The types for printing the inscription upon the ticket are arranged at right angles to the length of the shaft, which position admits of some lines of the inscription being printed in one color, and the remainder in another color. In the type frame a slot or opening is formed lengthwise of the shaft; and behind this opening are three numbering discs, and three discs for indicating the quantity of tickets numbered,—all standing in the same row. The numbering discs are made with raised figures, which project through the slot, in order to print the number upon the ticket; and on the peripheries of the registering discs (which move simultaneously with their corresponding numbering discs), the figures are engraved. The tickets to be printed and numbered are placed in a rectangular box or receiver, having at the bottom a flat sliding piece, which has a reciprocating motion for the purpose of pushing the lowest ticket out of the box, through an opening in the front side thereof, beneath an elastic pressing-roller of India-rubber; the type frame (with the types and figures properly inked), is at the same time brought, by the rotation of its shaft, into contact with the ticket beneath the pressing-roller, and as it continues its motion, it causes the ticket to move forward beneath the pressing-roller, and to be properly printed and numbered. The ticket then falls from the machine; and the type frame, carried on by the revolution of the shaft, brings that number on the registering discs, which corresponds with the number printed on the ticket, under a small opening in the case, covered with glass; whereby the number of tickets printed will be indicated.

Backing Books.—Not altogether foreign to the subject of printing is the contribution of Mr. C. Star, of New-York, United States, who exhibits two machines for booksellers' use,—the one being employed for backing, and the other for finishing the backs of books. The two machines are similar to each other, as regards the subordinate parts, but differ in some other respects. In the backing machine, the stitched sheets, forming the book, are fixed in a pair of iron clumps, somewhat larger than the book itself. The clumps are mounted on horizontal pivots, and furnished with a weighted lever, which gives them a tendency to move out of the vertical line, and thereby bring the back of the book, which stands up above the edges of the clumps, under the action of a smooth metal roller. This roller turns in bearings which are capable of sliding vertically in the framing of the machine; and the bearings are pressed upon by two weighted levers, when the machine is in use, so as to cause the roller to bear down forcibly upon the book. While the roller is in this position, the weighted lever of the clumps causes the book to oscillate, and thus the rounding of the back is effected. The movement of the clumps under the roller is regulated by the workman through a foot treadle, connected with the lever in the machine for finishing the backs; the roller is engraved with any suitable design; and the cross piece which supports its bearings, is made hollow, and is heated by steam, for the purpose of communicating heat to the roller. Motion in this case is given to the clump by a winch-handle, instead of the weighted lever, and the pattern on the roller is thereby embossed upon the back of the book.—*Newton's Journal.*

Washing and Mangling.—The British portion of the Great Exhibition contained numerous examples of the application of machinery to economize labor in the processes of washing, wringing, and mangling. The washing machines may be divided into three classes, viz., first, those which have a rotary action; secondly, those wherein vibrating beaters are employed; and thirdly, those in which vertical beaters are ultimately raised and permitted to fall upon the clothes.

In the first class, Mr. V. Price, of Wardour Street, Soho, has a simple machine, consisting of a cylinder or drum, to contain the clothes, revolving horizontally in a close wooden vessel, or outer case, which holds the soap-suds. The drum is made with solid ends; but (in order that the soap-suds may have free access to the clothes), the periphery or body thereof is composed of wooden bars or spokes, extending from one end to the other, with a space somewhat greater than the width of a bar between the adjacent bars, so as to resemble what is known to engineers as a "lantern drum." The clothes are introduced by opening a door in the side of the drum; and on rotary motion being given to the drum by a handle, the soap-suds will be caused to act upon and thoroughly cleanse the clothes.

Mr. J. Adams, of Selby, exhibited a machine, in which the articles to be washed were placed in a perforated wooden barrel or octagonal vessel, rotating horizontally in an outer case. Above the case two wooden rollers are mounted, one over the other; and the clothes, when sufficiently washed, are passed between such rollers, so as to squeeze out the soap-suds, instead of wringing the clothes by hand. These rollers may be subsequently used for mangling the clothes.

Another rotary machine, exhibited by Mr. Pearson, of Leeds, consists of a tub or wooden vessel, in which the clothes are thrown; and the requisite agitation for washing or discharging the dirt is effected by means of an upright beater, which rotates in the tub in the same manner as the "dasher" of an upright rotary churn. This apparatus is also provided with a pair of rollers for wringing and mangling the clothes.

The next machines of the rotary class which we shall notice, are those of Messrs. Manlove, Alliott, & Seyrig, of Lenton Works, Nottingham. In these machines the operations of washing and drying are effected by centrifugal force; that is on the mass-trundling principle. The utility of this construction of machines, both for washing and drying fabrics, is unquestionable; and, under slight modifications, they are extensively used for the refining of sugar. Each machine may be described as consisting simply of a drum, having its periphery formed of wires, and being fixed to a vertical shaft, which rotates in the centre of a cylindrical metal case. The goods to be washed are put into the drum, and water is supplied thereto through a hollow central shaft. On rapidly rotating the drum, the water is caused, by centrifugal force, to pass outwards through the goods, and through the wire periphery of the drum, into the outer case, from which it is conducted away. To dry washed, or wet goods, they are placed in the drum without access of water, and by the rapid rotation of the same the moisture in the clothes is discharged,—the time required for drying in no case exceeding five minutes. These machines are suitable for washing and rinsing dyed goods; but they are not applicable to the washing of thoroughly dirty clothes; they may, however, be used for rinsing the same after they have been washed by other means.

Mr. Robinson exhibited a machine for drying wet clothes, which acts upon the same principle as the above. The drum that receives the wet clothes is formed of round iron bars, with spaces between them, and mounted on a horizontal shaft. By means of a row of bars the drum is divided into two compartments, which receive the goods through a door formed in the drum-ends; and the whole is enclosed in a circular iron case, which is open below. The goods having been put into the drum, it is caused to revolve with great rapidity, and the moisture is expressed from the goods by centrifugal force, and escapes through the opening in the bottom of the case. See HYDRO-EXTRACTOR.

Another rotary washing machine is exhibited by Mr. Nunn. It consists of a large drum, which is mounted upon a horizontal shaft, within a closed vessel or case, and carries numerous small rollers all round its periphery, such rollers being capable of turning freely and independently of each other, and their axes being parallel to the axis of the drum. The case contains water or soap-suds, in which the drum is immersed to the extent of about one-fifth or one-sixth of its diameter; the clothes are kept in contact with the drum, as it revolves by several endless tapes; and as the clothes successively arrive at the upper part of the drum, they are acted upon by five fluted rollers above it.

Mr. Nunn contributed another machine, which appears to be designed for rinsing and wringing only. Two fluted rollers, one above the other, are mounted in the upper part of a wooden vessel or trough; an endless band passes over the lower roller, for the purpose of conducting the clothes between the fluted rollers; and there is another endless band below, immersed in the water which the vessel contains, and passing over a roller at each end of the vessel, its apparent use being to receive the clothes as they fall from the first band, and bring them again to that end of the vessel where they were introduced.

Machines of the second class, viz. those wherein vibrating beaters are employed, were exhibited by Messrs. Fryer, Tasker, Marsden and Reid. In Mr. Fryer's machines, an upright board or beater, having vertical slots or openings in it, is caused to vibrate or swing to and fro in a segmental vessel (containing the clothes to be washed and a suitable quantity of soap-suds), and beat the clothes against the side of the vessel until they are thoroughly cleansed.

In Mr. Tasker's machine, a beater, with vertical slots or openings in it, vibrates in a trough or vessel having a series of projecting ribs at each side, corresponding with the openings in the beater.

The beater in Mr. Marsden's machine has a projecting rib affixed to it on each side, between the several slots or openings; and at each side of the segmental trough or vessel, in which the beater works, there is hinged a flap or false side, with numerous horizontal slots or openings in it.

The three last-mentioned machines are all provided with rollers for wringing and mangling the clothes.

Mr. Reid's machine consists of a large square box, the bottom of which takes the form of the segment described by a vibrating beater suspended in the box. The machine also contains a "wringer," which is a net formed into a bag, having an opening at the side for the introduction of the wet clothes; and at each end of the bag there is a screw bolt, with a nut upon it, by one of which the bag is to be secured to the side of the machine, and by the other it is connected to a crank, which, on being actuated, will twist the bag, and thereby express the water from the clothes. At the back of the machine several rollers are mounted one above the other, for the purpose of mangling the articles.

Mr. W. Macalpine, of Hammersmith, exhibited a machine of the third class, constructed with ascending and descending beaters. It consists of a cylindrical metal vessel, which is fixed upon an upright axis, and is caused to rotate by suitable wheel-work in connection with a steam-engine. The vessel is made with perforated false bottom and sides, so as to form a hollow casing, into which steam may be admitted, and may thence pass through the perforations, and act upon the water and the fabrics to be washed. The process of agitating or washing the fabrics is effected by nine or ten upright beaters, arranged in a row across the interior of the vessel, and alternately elevated and permitted to fall upon the fabrics.

Messrs. Wilkinson, Stutterd, Baker, Moreton, and others, exhibited machines for performing the operation of mangling only; but as these, whatever their respective merits, cannot be said to be new applications of machinery for economizing labor, they do not properly come within our province.

From the above notice it will be seen that considerable attention has been given by machine makers to that most important branch of domestic economy—washing. There is not, perhaps, one of the machines above described, which would not as effectually cleanse all under-clothing as the most fastidious could desire; and yet we still suffer our clothes to be tortured by the rubbing and wringing of those merciless modern amazons who preside over soap-suds, and allow them to be transformed into lint and ribbons, without an attempt at removing the annoyance; indeed, so inveterate is prejudice, that the washerwoman may yet look for a long lease of her profession, as it luckily touches upon no established manufacture.

While on the subject of washing, we may direct attention to a machine exhibited by Mr. C. Farrow, of Great Tower street, for washing bottles. In this machine a horizontal metal spindle, carrying a bottle brush at each end, is caused to revolve by being connected with a treadle. A bottle is pushed over each brush by the operator, who holds the bottles one in each hand, whilst by means of his foot he works the treadle and causes the rotation of the brushes.

Knife-cleaning.—Specimens of those very useful machines which have lately been introduced for cleaning knives and forks are to be found in the building, and demand some notice. Mr. Kent's machine consists of a box or case, containing a couple of wooden discs, fixed near to each other upon a horizontal iron rod or spindle, which passes through the case, and is caused to rotate by means of a winch-handle. Each disc is, for about three-fourths of the area of its inner face, covered with alternate rows of bristles and strips of leather; and the remaining fourth part is covered with bristles only. The knife-blades to be cleaned are introduced through openings in the case, between the rubbing surfaces of the discs; and rotatory motion being given to the discs by a winch-handle, the knives are rapidly cleaned and polished.

The machines exhibited by Mr. Masters are constructed upon the same plan as the above; but the rubbing surface of each disc is formed of strips of buff leather, with only a narrow circle of bristles around the edge of each surface, to clean the shoulders of the knives; small brushes are fixed beneath the holes in the case, through which the blades of the knives are inserted, to prevent the exit of dust from the apparatus.

Mr. Price exhibited a machine for cleaning knives, and another for cleaning forks. The knife-cleaner consists of a horizontal drum, covered with pieces of leather or felt, and fixed within another drum or circular framing, lined with leather or felt. The knives are introduced through openings, in a movable circular plate, at the front of the outer casing, and enter between the surfaces of the two drums. The plate is fixed upon a horizontal axis, which extends through the case, and is furnished at the back with a handle; by turning which the disc is caused to rotate and carry round the long rectangular opening in the side, behind which two brushes are fixed face to face. Between these brushes the prongs of the forks are introduced, and the handles are secured in a carrier, which is made to advance and recede alternately by means of a throw-crank, and thereby thrust the prongs into and draw them out of contact with the brushes. The carrier consists of two metal plates, the lower one carrying a cushion of vulcanized India-rubber for the fork handles to rest upon, and the upper being lined with leather; they are hinged together at one end, and are connected at the other, when the handles have been placed between them, by a thumb-screw.

Chopping-knife.—The same exhibitor also contributed a chopping-knife for the reduction of suet, &c., into small particles. It consists of three blades fixed side by side, to the lower surface of a flat metal frame, which is hinged at one end to a fixed metal pillar or support, and at the other is provided with a handle, whereby the blades are alternately lifted and brought down upon the suet or other substance to be chopped, which is laid upon a circular wooden dish or chopping-block. Each time that the knife-frame is raised, a hooked rod, suspended therefrom, catches into the teeth of a ratchet wheel, and turns it partly round; on the axis of this ratchet wheel is a small cog-wheel, which takes into the teeth of a circular rack or wheel, fixed to the underside of the chopping-block; and thus, at each ascent of the knife-frame, the block will be moved partly round, and made to present fresh portions of suet to the action of the descending knives.—*Newton's Journal*, xxxix. 182.

Envelope folding.—In the envelope folding machine of Messrs. De la Rue & Co. each piece of paper previously cut by a fly press into the proper form, for making an envelope (and having the emblematical stamp or wafer upon it), is laid by the attendant on a square or rectangular metal frame or box, formed with a short projecting piece at each corner, to serve as guides to the paper, and furnished with a movable bottom, which rests on helical springs. A presser at the end of a curved compound arm (which moves in a vertical plane), then descends and presses the paper down into the box—the bottom thereof yielding to the pressure; and thereby the four ends or flaps of the piece of paper are caused to fly up; the presser may be said to consist of a rectangular metal frame, the ends of which are attached to the outer part of the curved arm, and the sides thereof to the inner portion of the arm; so that the ends and sides of the presser can move independently of each other. The ends of the presser then rise, leaving the two sides of it still holding down the paper; two little lappet pieces next fold over the two side flaps of the envelope; and immediately a horizontal arm advances, carrying a V shaped piece charged with adhesive matter or cement (from a saturated endless band), and applies the same to the two flaps. A third lappet presses down the third flap of the envelope upon the two cemented flaps, and thereby causes it to adhere thereto; and then a pressing piece of the same size as the finished envelope, folds over the last flap and presses the whole flat. The final operation is to remove the envelope, and this is effected by a pair of metal fingers, with India-rubber ends, which descend upon the envelope, and, moving sideways, draw the envelope off the bottom of the box (the pressing-piece having moved away and the bottom of the box risen to the level of the platform of the machine) on to a slowly moving endless band, which gradually carries the finished envelopes away. A fresh piece of paper is laid upon the box or frame, and the above operations are repeated.

The working of this ingenious machine appeared to be one of the chief attractions of the Exhibition, but another, for the same object, invented by Mr. A. Remond, of Birmingham, and shown in operation by Messrs. Waterlow & Sons, of London Wall, was equally deserving attention. The distinguishing feature of this arrangement is the employment of atmospheric pressure to feed in the paper which is to form the envelope, and to deflect the flaps of the envelope into inclined positions, to facilitate the action of a plunger, which descends to complete the folding. The pieces of paper, cut to the proper form, are laid on a platform, which is furnished with a pin at each corner to enter the notches in the pieces of paper, and retain them in the proper position, and such platform is caused alternately to rise and bring the upper piece of paper in contact with the instrument that feeds the folding part of the machine, and then to descend until a fresh piece is to be removed. The feeding instrument consists of a horizontal hollow arm, with two holes in the under side, and having a reciprocating movement. When it moves over the upper piece of paper on the platform, a partial vacuum is produced within it, by a suitable exhausting apparatus, and the paper is thereby caused to adhere to it at the holes in its under surface by the pressure of the atmosphere. The instrument carries the paper over a rectangular recess or box, and then, the vacuum within it being destroyed, it deposits the paper between four pins, fixed at the angles of the box, and returns for another piece of paper. As the paper lies on the top of the box, the flap, which will be undermost in the finished envelope, is pressed by a small bar or presser on to the upper edge of two angular feeders, communicating with a reservoir of cement or adhesive matter, and thereby becomes coated with cement; and, at the same time, the outermost or seal flap may be stamped with any required device, by dies, on the other side of the machine. A rectangular frame or plunger now descends and carries the paper down into the box; the plunger rises, leaving the flaps of the envelope upright; streams of air, issuing from a slot in each side of the box, then cause the flaps to incline inwards; and the folding is completed by the plunger again descending, the interior and under surface of such plunger being formed with projecting parts, suitable for causing the several flaps to fold in the proper order. The bottom of the box (which is hinged) opens,

and discharges the envelope down a shoot on to a table below; the feeding instrument then brings forward another piece of paper; and a repetition of the above movements takes place.

A machine for a somewhat similar purpose to the above was exhibited by Mr. J. Black, of Edinburgh. The object of this machine is to fold printed sheets of paper, and it is proportioned to fold them to the octavo size; but machines may be made, on the same principle, to suit books or pamphlets of other sizes. To fold sheets for an octavo book, three movements are required, viz.: first, to fold the sheet to half size; secondly, to double it at right angles; and thirdly, to double it again at right angles to the last fold. In the machine these movements are effected by three blades or knives, which are formed with serrated edges, to prevent the paper slipping. The blades are affixed, at one end, to separate shafts or spindles, which simultaneously perform part of a revolution in either direction alternately, and so cause the outer end of each blade to describe an arc of about the fourth part of a circle; and as the actions of the knives are simultaneous, the machine contains three sheets, in different states of progression at the same time. The sheet of paper is laid on a horizontal platform, in such a position that the first blade in descending will come across that part of the paper where the first fold is to be made,—draw the sheet through a slot or opening made in the platform, and carry it down into a narrow vertical passage, or chamber; by which means it will be folded in half, and left in a vertical position. The second blade (which vibrates in a horizontal plane), then comes in contact with the central part of the doubled sheet, and folds it at that part, by drawing it into a narrow horizontal passage,—leaving such fold in a line at right angles to the vertical passage. The third blade (which vibrates in a vertical plane parallel to the first blade) draws the sheet down a vertical passage, so as to fold it again, and brings it to a pair of vertical delivering rollers, which pass it from the machine. Accuracy in laying the sheets upon the platform is insured by an arrangement, consisting of a short adjustable straight edge, set parallel to the first blade, and of a projecting nob, set in the same parallel line. The attendant, who feeds the machine, takes hold of the sheet at the edge of the letter-press, and thus lays it on the platform in such a manner that his fingers come in contact with the straight-edge and nob,—whereby the central line of the sheet will be caused to lie exactly over the central slot in the platform; the position of the nob also indicates the point where the corner of the letter-press should be, in order that the subsequent folding in the opposite direction may be accurately performed. This is a very ingenious and efficient contrivance, and is well deserving the attention of bookbinders.

Paging Books.—A self-acting machine for paging books and numbering documents was exhibited by Messrs. Waterlow & Sons, and shown in operation. As this class of machines has of late come into extensive use, owing to the protection which is afforded to the merchant and the tradesman by the consecutive paging of account and other manuscript books, it may be well to explain the general construction of the numbering apparatus, and its mode of operation, more especially as it forms an important adjunct to some machines which we shall hereafter have occasion to notice. The numbering apparatus consists of five discs, which are provided with raised figures on their periphery, running from 1, 2, 3, &c., to 0; and these figures serve (like letter-press type) to print the numbers required. The discs are mounted at the outer end of a vibrating frame or arm on a common shaft, to which the first or units disc is permanently fixed; and the other four discs (viz., those for making tens, hundreds, thousands, and tens of thousands,) are mounted loosely thereon, so that they need not, of necessity, move when the shaft is rotating; but they are severally caused to move in the following order:—the tens disc performs one-tenth of a revolution for every revolution of the units disc, and so on. As the discs rise from the paper after every impression, the units disc is caused to perform one-tenth of a revolution (in order that the next number printed may be a unit greater than the preceding one), by a driving click taking into the teeth of a ratchet-wheel, fixed on the left hand end of the shaft. The movement of the other discs is effected, at intervals, by means of a spring-catch, affixed to the side of the units disc, and rotating therewith; which catch, each time that the units disc completes a revolution, is caused by a projection on the inner surface of the vibrating frame to project behind one of the raised figures on the tens disc, and carry it round one-tenth of a revolution on the next movement of the units disc taking place; and then, the catch having passed away from the projection, no further increase in the number imprinted by the tens disc will be effected until the units disc has performed another revolution. Every time that the tens disc completes a revolution, the spring-catch causes the hundreds disc to move forward one-tenth of a revolution, and similar movements are imparted to the remaining discs at suitable times. The shaft is prevented from moving except when it is acted on by the driving click, by a spring detent, or pull entering the notches in

the periphery of a wheel fixed on the right-hand end of the shaft; and thus the discs are held steady while numbering, and a clear and even impression of the figures is ensured. The leaves of the book to be paged or numbered are laid on the raised part of the table of the machine, covered with vulcanized india-rubber, and as each page is numbered it is turned over by the attendant, so as to present a fresh page on their next descent. As the discs ascend after numbering each page, an inking apparatus (consisting of three rollers, mounted in a swing frame and revolving in contact with each other, so as to distribute the ink which is fed to the first roller evenly on to the third or inking roller), descends and inks the figures which are to be brought into action when the numbering apparatus next descends. By this means books or documents may be paged or marked with consecutive numbers; for printing duplicate sets of numbers, as for bankers' books, a simple and ingenious contrivance is adopted. This consists in the employment of an additional ratchet-wheel, which is acted on by the driving click that moves the ratchet-wheel above mentioned, and is provided with a like number of teeth to that wheel. But the diameter of the additional ratchet-wheel is increased to admit of the teeth being so formed that the driving click will be thereby held back from contact with every alternate tooth of the first mentioned ratchet-wheel; and thus the arrangement of the numbering discs will remain unchanged, to give, on their next descent, a duplicate impression of the number previously printed; but, on the reascending of the numbering apparatus, the click will act on a tooth of both ratchet-wheels, and move both forward one-tenth of a revolution; and as the shaft accompanies the first ratchet-wheel in its movements, the number will consequently be changed.

Messrs. Schlesinger & Co. also exhibited a paging machine, the capabilities of which are similar to the above, but somewhat differently obtained. The numbering discs in this instance are provided with ten teeth, with a raised figure on the end of each tooth; and they receive the change motion from cog-wheels mounted below them on the same frame. At each descent of the frame a stationary spring-catch or hook-piece drives round the wheel one tooth, that gears into the teeth of the units disc, and thereby causes the units disc to bring forward a fresh figure. The toothed wheels are somewhat narrower than the numbering discs, but one tooth of each wheel is enlarged laterally to about double the size of the other teeth; so that at the completion of every revolution of the wheel the projecting tooth shall act upon a tooth of the next disc, and carry that disc forward one tenth of a revolution. By this means the requisite movements of the discs for effecting the regular progression of the numbers are produced; the first wheel driving its own disc, and communicating motion at intervals to the next disc, and the other wheels each receiving motion at intervals from the disc with which it is connected, and transmitting motion, at still greater intervals of time, to the next disc.

The machine is caused to print the figures in duplicate by drawing the spring-catch out of action at every alternate descent of the frame, and thereby preventing any change of the figures taking place until after the next impression.

The numbers may be increased two units at each impression, so as to print all even or all odd numbers, by bringing a second catch into action, which causes the unit disc to advance one step during the ascending movement of the frame, in addition to the advance during the descent of the same.—*Newton's Journal*, xxxviii. 430.

LABRADORITE, opaline, or Labradore feldspar, is a beautiful mineral, with brilliant changing colors, blue, red, and green, &c. Spec. grav. 2.70 to 2.75. Scratches glass; affords no water by calcination; fusible at the blowpipe into a frothy bead; soluble in muriatic acid; solution affords a copious precipitate with oxalate of ammonia. Cleavages of $93\frac{1}{2}^{\circ}$ and $86\frac{1}{2}^{\circ}$; one of which is brilliant and pearly. Its constituents are silica, 55.75; alumina, 26.5; lime, 11; soda, 4; oxyde of iron, 1.25; water, 0.5.

LABYRINTH, in metallurgy, means a series of canals distributed in the sequel of a stamping-mill; through which canals a stream of water is transmitted for suspending, carrying off, and depositing, at different distances, the ground ores. See **METALLURGY**.

LAC, LAC-DYE (*Laque*, Fr.; *Lack*, *Lackfarben*, Germ.). *Stick-lac* is produced by the puncture of a peculiar female insect, called *coccus lacca* or *ficus*, upon the branches of several plants; as the *ficus religiosa*, the *ficus indica*, the *rhamnus fijiuba*, the *croton lacciferum*, and the *butea frondosa*, which grow in Siam, Assam, Pegu, Bengal, and Malabar. The twig becomes thereby incrustated with a reddish mammelated resin, having a crystalline-looking fracture.

The female lac insect is of the size of a louse; red, round, flat, with 12 abdominal circles, a bifurcated tail, antennæ, and 6 claws, half the length of the body. The male is twice the above size, and has 4 wings; there is one of them to 5000 females. In November or December the young brood makes its escape from the eggs, lying beneath the dead body of the mother; they crawl about a little way, and fasten themselves to the bark of the shrubs. About this period the branches often swarm to such a degree with this vermin, that they seem covered with a red dust; in this case, they are apt to dry up, by being exhausted of their juices. Many of these insects, however, become the

Layton, Hulbert, & Co.'s Circular, 7th Jan., 1852.

The market prices on 8th Jan. 1852 were from 3d. to 2s. 4d. per lb.

LACCIC ACID crystallizes, has a wine-yellow color, a sour taste, is soluble in water, alcohol, and ether. It was extracted from stick-lac by Dr. John.

LACCINE is the portion of shell-lac which is insoluble in boiling alcohol. It is brown, brittle, translucent, consisting of agglomerated pellicles, more like a resin than any thing else. It is insoluble in ether and oils. It has not been applied to any use.

LACE BOBBINET. Hitherto the threads of silk, flax, or cotton, used as the chain or warp in the manufacture of lace or net, have been warped, or ranged side by side, and in this state wound upon a cylinder, which being mounted upon an axle or shaft, delivers the warp threads as each mesh of the net is formed. By the patented arrangement of Mr. W. E. Newton, whatever may be the difference in the consumption of the several threads to produce the fabric, in comparison with other portions of the warp, the cylinder will always deliver the same quantity in length of each thread. This

gives rise to great inconvenience. According to the present invention, for every thread a bobbin is provided for regulating its tension; and thus each separate thread or number of threads may, without inconvenience, furnish a greater or less length of warp as may be required. See the details, with figures, in *Newton's London Journal*, xxxv. 391.

LACE MANUFACTURE. The pillow-made, or bone-lace, which formerly gave occupation to multitudes of women in their own houses, has, in the progress of mechanical invention, been nearly superseded by the bobbin-net lace, manufactured at first by hand-machines, as stockings are knit upon frames, but recently by the power of water or steam. This elegant texture possesses all the strength and regularity of the old Buckingham lace, and is far superior in these respects to the point-net and warp lace, which had preceded, and in some measure paved the way for it. Bobbin-net may be said to surpass every other branch of human industry in the complex ingenuity of its machinery; one of Fisher's spotting frames being as much beyond the most curious chronometer, in multiplicity of mechanical device, as that is beyond a common roasting-jack.

The threads in bobbin-net lace form, by their intertwisting and decussation, regular hexagonal holes or meshes, of which the two opposite sides, the upper and under, are directed along the breadth of the piece, or at right angles to the selvage or border.

833

Fig. 833 shows how, by the crossing and twisting of the threads, the regular six-sided mesh is produced, and that the texture results from the union of three separate sets of threads, of which one set proceeds downwards in serpentine lines, a second set proceeds from the left to the right, and a third from the right to the left, both in slanting directions. These oblique threads twist themselves round the vertical ones, and also cross each other betwixt them, in a peculiar manner, which may be readily understood by examining the representation. In comparing bobbin-net with a common web, the perpendicular threads in the figure, which are parallel to the border, may be regarded as the warp, and the two sets of slanting threads, as the weft.

These warp threads are extended up and down, in the original mounting of the piece, between a top and bottom horizontal roller or beam, of which one is called the warp beam, and the other the lace beam, because the warp and finished lace are wound upon them respectively. These straight warp threads receive their contortion from the tension of the weft threads twisted obliquely round them alternately to the right and the left hand. Were the warp threads so tightly drawn that they became inflexible, like fiddle-strings, then the lace would assume the appearance shown in fig 834; and although this condition does not really exist, it may serve to illustrate the structure of the web. The warp threads stand in the positions $a\ a'$, and $a''\ a'''$; the one half of the weft proceeds in the direction $b\ b'$, $b''\ b'''$, and $b'''\ b''''$; and the second crosses the first by running in the direction $c\ c'$, or $c''\ c'''$, towards the opposite side of the fabric. If we pursue the path of a weft thread, we find it goes on till it reaches the outermost or last warp thread, which it twists about; not once, as with the others, but twice; and then returning towards the other border, proceeds in a reverse direction. It is by this double twist, and by the return of the weft threads, that the selvage is made.

834

The ordinary material of bobbin-net is two cotton yarns, of from No. 180 to No. 250, twisted into one thread; but sometimes strongly twisted single yarn has been used. The beauty of the fabric depends upon the quality of the material, as well as the regularity and smallness of the meshes. The number of warp threads in a yard in

breadth is from 600 to 900; which is equivalent to from 20 to 30 in an inch. The size of the holes cannot be exactly inferred from that circumstance, as it depends partly upon the oblique traction of the threads. The breadth of the pieces of bobbin-net varies from edgings of a quarter of an inch, to webs 12, or even 20 quarters, that is, 5 yards wide.

Bobbin-net lace is manufactured by means of very costly and complicated machines, called *frames*. The limits of this Dictionary will admit of an explanation of no more than the general principles of the manufacture. The threads for crossing and twisting round the warp, being previously gassed, that is, freed from loose fibres by singeing with gas, are wound round small pulleys, called bobbins, which are, with this view, deeply grooved in their periphery. *Figs. 835, 836, exhibit the bobbin alone, and with its carriage.*

836

In the section of the bobbin *a*, *fig. 835*, the deep groove is shown in which the thread is wound. The bobbin consists of two thin discs of brass, cut out in a stamp-press, in the middle of each of which there is a hollow space *c*. These discs are riveted together, leaving an interval between their edge all round, in which the thread is coiled. The round hole in the centre, with the little notch at top, serves for spitting them upon a feathered rod, in order to be filled with thread by the rotation of that rod in a species of reel, called the bobbin-filling machine. Each of these bobbins (about double the size of the figure), is inserted into the vacant space *c*, of the carriage, *fig. 836*. This is a small iron frame (also double the size of the figure), which, at *e e*, embraces the grooved border of the bobbin, and by the pressure of the spring at *f*, prevents it from falling out. This spring serves likewise to apply sufficient friction to the bobbin, so as to prevent it from giving off its thread at *g* by its rotation, unless a certain small force of traction be employed upon the thread. The curvilinear groove *h h*, sunk in each face or side of the carriage, has the depth shown in the section at *h*. This groove corresponds to the interval between the teeth of the comb, or bars of the bolt, in which each carriage is placed, and has its movement. A portion of that bolt or comb is shown at *a*, *fig. 837* in plan, and one bar of a circular bolt machine at *b*, in section. If we suppose two such combs or bolts placed with the ends of the teeth opposite each other, but a little apart, to let the warp threads be stretched, in one vertical plane, between their ends or tips, we shall have an idea of the skeleton of a bobbin-net machine. One of these two combs, in the double bolt machine, has an occasional lateral movement called *shogging*, equal to the interval of one tooth or bolt, by which, after it has received the bobbins,

with their carriages, into its teeth, it can shift that interval to the one side, and thereby get into a position to return the bobbins, with their carriages, into the next series of interstices or gates, in the other bolt. By this means the whole series of carriages receives successive side steps to the right in one bolt, and to the left in the other, so as to perform a species of countermarch, in the course of which they are made to cross and twist round about the vertical warp threads, and thus to form the meshes of the net.

The number of movements required to form a row of meshes in the double tier machine, that is, in a frame with two combs or bars, and 2 rows of bobbins, is six; that is,

the whole of the carriages (with their bobbins) pass from one bar or comb to the other six times, during which passages the different divisions of bobbin and warp threads change their relative positions 12 times.*

This interchange or traversing of the carriages with their bobbins, which is the most difficult thing to explain, but at the same time the most essential principle of the lace-machine, may be tolerably well understood by a careful study of *fig. 838*, in which the

simple line ψ represents the bolts or teeth, the sign ϕ the back line of carriages, and the sign ϕ the front line of carriages. II is the front comb or bolt bar, and I the back bolt bar. The former remains always fixed or stationary, to receive the carriages as they may be presented to it by the shogging of the latter. There must be always one odd carriage at the end; the rest being in pairs.

No. 1 represents the carriages in the front comb or bar, the odd carriage being at the left end. The back line of carriages is first moved on to the back bar I, the odd carriage, as seen in No. 1, having been left behind, there being no carriage opposite to drive it over to the other comb or bar. The carriages then stand as in No. 2. The bar I now shifts to the left, as shown in No. 3; the front carriages then go over into the back bar or comb, as is represented by No. 4. The bar I now shifts to the right, and gives the position No. 5. The front carriages are then driven over to the front bar, and leave the odd carriage on the back bar at the right end, for the same reason as before described, and the carriages stand as shown in No. 6. The bar I next shifts to the left, and the carriages stand as in No. 7 (the odd carriage being thereby on the back bar to the left.) The back carriages now come over to the front bar, and stand as in No. 8. The back bar or comb I shifts to the right as seen in No. 9, which completes the traverse. The whole carriages with their bobbins have now changed their position, as will be seen by comparing No. 9 with No. 1. The odd carriage, No. 1 ϕ has advanced one step to the right, and has become one of the front tier; one of the back tier or line ϕ has advanced one step to the left, and has become the odd carriage; and one of the front ones ϕ has gone over to the back line. The bobbins and carriages throughout the whole width of the machine have thus crossed each other's course, and completed the mesh of net.

The carriages with their bobbins are driven a certain way from the one comb to the other, by the pressure of two long bars (one for each) placed above the level of the comb, until they come into such a position that their projecting heels or catches *i i*, *fig. 611*, are moved off by two other long flat bars below, called the locker plates, and thereby carried completely over the interval between the two combs.

There are six different systems of bobbin-net machines. 1. Heathcoat's patent machine. 2. Brown's traverse warp. 3. Morley's straight bolt. 4. Clarke's pusher principle, single tier. 5. Leaver's machine, single tier. 6. Morley's circular bolt. All the others are mere variations in the construction of some of their parts. It is a remarkable fact, highly honorable to the mechanical judgment of the late Mr. Morley of Derby, that no machines except those upon his circular bolt principle have been found capable of working successfully by mechanical power.

The circular bolt machine (comb with curved teeth) was used by Mr. Morley, for making narrow breadths or edgings of lace immediately after its first invention, and it has been regularly used by the trade for that purpose ever since, in consequence of the inventor having declined to secure the monopoly of it to himself by patent. At that time the locker bars for driving across the carriages had only one plate or blade. A machine so mounted is now called "the single locker circular bolt." In the year 1824, Mr. Morley added another plate to each of the locker bars, which was a great improvement on the machines for making plain net, but an obstruction to the making of narrow breadths upon them. This machine is now distinguished from the former by the term "double locker."*

A rack of lace, is a certain length of work counted perpendicularly, and contains 240 meshes or holes. Well-made lace has the meshes a little elongated in the direction of the selvege.

* By reading the above brief account of Bobbin-net, in connection with the most detailed description of it in my COTTON MANUFACTURE OF GREAT BRITAIN, a tolerably clear conception of the nature of this intricate manufacture may be obtained.

The term gauge, in the lace manufacture, means the number of gates, slits, or interstices, in one inch of the bolt-bar or comb; and corresponds therefore to the number of bobbins in an inch length of the double tier. Thus, when we say "gauge nine points," we mean that there are nine gates with nine bobbins in one inch of the comb or bolt-bar. Each of such bobbins with its carriage is therefore no more than one ninth of an inch thick. The common proportion or gauge up and down the machine is 16 holes in the inch for ten bobbins transversely. Circular bolt double tier machines can turn off by steam power fully 360 racks each day of 18 hours, with a relay of superintendents.

The number of new mechanical contrivances to which this branch of manufacture has given rise, is altogether unparalleled in any other department of the arts. Since Mr. Heathcote's first successful patent, in 1809, a great many other patents have been granted for making lace. In the year 1811, Mr. Morley, then of Nottingham, invented his straight bolt frame, more simple in construction, better combined, and more easy in its movements, than the preceding machines; but the modest inventor did not secure it, as he might have done, by patent. The pusher machine was invented in the same year, by Samuel Mart and James Clark, also of Nottingham. The following year is remarkable in the history of the lace trade, for the invention of the circular bolt machine, by Mr. Morley—a mechanism possessing all the advantages of his straight bolt machine, without its disadvantages.

Nearly at the same time Mr. John Leaver brought forward the lever machine, conjointly with one Turton, both of New Radford, near Nottingham. About the year 1817 or 1818, Mr. Heathcote applied the rotatory movement to the circular bolt machine, and mounted a manufactory on that plan, by mechanical power, at Tiverton, after he and his partner, Mr. Boden, had been driven from Loughborough, in 1816, by the atrocious violence of the frame-destroying Luddites.

Such has been the progress of improvement and economy in this manufacture, that the cost of labor in making a rack, which was, twenty years ago, 3s. 6d., or 42 pence, is now not more than one penny. The prices of this beautiful fabric have fallen in an equally remarkable manner. At the former period, a 24 rack piece, five quarters broad, fetched 17l. sterling, in the wholesale market; the same is now sold for 7s. The consequence is, that in lace decoration, the maid servant may be now more sumptuously arrayed than her mistress could afford to be twenty years ago.

LACKER, is a varnish, consisting chiefly of a solution of pale shellac in alcohol tinged with saffron, annatto, or other coloring matter. See VARNISH.

LACTIC ACID. (*Acide Lactique*, Fr.; *Milchsäure*, Germ.) This acid was discovered by Scheele in buttermilk, where it exists most abundantly; but it is present also in fresh milk in small quantity, and communicates to it the property of reddening litmus. Lactic acid may be detected in all the fluids of the animal body; either free or saturated with alkaline matter.

Scheele obtained this acid by evaporating the sour whey of clotted milk to an eighth part of its bulk, saturating this remainder with slaked lime, in order to throw down the subphosphate of lime held in solution, filtering the liquor, diluting it with thrice its weight of water, and precipitating the lime circumspectly, by the gradual addition of oxalic acid. He next filtered, evaporated to dryness on a water bath, and digested the residuum in strong alcohol, which dissolved the lactic acid, and left the sugar of milk. On evaporating off the alcohol, the acid was obtained. As thus procured, it requires to be purified by saturation with carbonate of lead (pure white lead), and precipitating the solution of this lactate with sulphate of zinc, not added in excess. Sulphate of lead falls, and the supernatant lactate of zinc being evaporated affords crystals at first brown, but which become colorless on being dissolved and recrystallized twice or thrice. If the sulphuric acid of the dissolved salt be thrown down by water of baryta, the liquid when filtered and evaporated yields a pure lactic acid, of a syrupy consistence, colorless and void of smell. It has a pungent acid taste, which it loses almost entirely when moderately diluted with water. It does not crystallize. Its salts, with the exception of those of magnesia and zinc, have a gummy appearance, and are very soluble in alcohol, unless they hold an excess of base. Lactic acid consists of 44.92 carbon; 6.55 hydrogen; 48.53 oxygen. It contains 9.92 per cent. of water. It has not hitherto been applied to any use in the arts, except by the Dutch in their old process of bleaching linen with sour milk. See FERMENTATION.

New method of preparing.—The following process for procuring lactic acid and the lactates is so simple, as to merit a preference over all others heretofore proposed; it is as follows:—"Take 3 or 4 (litre = 1.76 pint) of milk, into which you pour a solution of from 200 to 300 grammes (gramme = 15.438 grs. Troy) of sugar of milk; the liquor is exposed to the air in an open vessel for some days, at a temperature of from 59° to 68° Fahr. It will then be found to have become very acid, and is to be saturated with bicarbonate of soda. After the lapse of 24 or

36 hours it becomes again acid, and must be saturated anew, repeating the process, until the whole of the sugar of milk has been converted into lactic acid. When it is considered that the transformation is complete, the milk must be boiled to coagulate the caseum; the liquid is next to be filtered and evaporated to the consistence of a syrup, taking care that the temperature be moderate. The product of evaporation is taken up by alcohol at 38°, which dissolves the lactate of soda. Into this alcoholic solution an adequate quantity of sulphuric acid is to be poured; the resulting sulphate of soda falls down, and the liquor by filtration and evaporation affords lactic acid almost pure. To obtain it in a state of great purity, it may be saturated with chalk; the lactate of lime crystallizes directly in white granules, whence we can separate the lactic acid by the ordinary means.

It is evident the lactic acid may be saturated with any other base, and afford expeditiously crystallized lactates.

LACTOMETER is the name of an instrument for estimating the quality of milk, called also a *Galactometer*. The most convenient form of apparatus would be a series of glass tubes each about 1 inch in diameter, and 12 inches long, graduated through a space of 10 inches, to tenths of an inch, having a stop-cock at the bottom, and suspended upright in a frame. The average milk of the cow being poured in to the height of 10 inches, as soon as the cream has all separated at top, the thickness of its body may be measured by the scale; and then the skim-milk may be run off below into a hydrometer glass, in order to determine its density, or relative richness in caseous matter, and dilution with water.

LAKES. Under this title are comprised all those colors which consist of a vegetable dye, combined by precipitation with a white earthy basis, which is usually alumina. The general method of preparation is to add to the colored infusion a solution of common alum, or rather a solution of alum saturated with potash, especially when the infusion has been made with the aid of acids. At first only a slight precipitate falls, consisting of alumina and the coloring matter; but on adding potash, a copious precipitation ensues, of the alumina associated with the dye. When the dyes are not injured, but are rather brightened by alkalis, the above process is reversed; a decoction of the dye-stuff is made with an alkaline liquor, and when it is filtered, a solution of alum is poured into it. The third method is practicable only with substances having a great affinity for subsulphate of alumina; it consists in agitating recently precipitated alumina with the decoction of the dye.

Yellow lakes are made with a decoction of Persian or French berries, to which some potash or soda is added; into the mixture a solution of alum is to be poured as long as any precipitate falls. The precipitate must be filtered, washed, and formed into cakes, and dried. A lake may be made in the same way with quercitron, taking the precaution to purify the decoction of the dye-stuff with buttermilk or glue. After filtering the lake it may be brightened with a solution of tin. Annatto lake is formed by dissolving the dye-stuff in a weak alkaline ley, and adding alum water to the solution. Solution of tin gives this lake a lemon yellow cast; acids a reddish tint.

Red lakes.—The finest of these is *carmine*.

This beautiful pigment was accidentally discovered by a Franciscan monk at Pisa. He formed an extract of cochineal with salt of tartar, in order to employ it as a medicine, and obtained, on the addition of an acid to it, a fine red precipitate. Homberg published a process for preparing it, in 1656. Carmine is the coloring matter of cochineal, prepared by precipitation from a decoction of the drug. Its composition varies according to the mode of making it. The ordinary carmine is prepared with alum, and consists of *carminium* (see COCHINEAL), a little animal matter, alumina, and sulphuric acid. See CARMINE.

Carminated lake, called lake of Florence, Paris, or Vienna. For making this pigment, the liquor is usually employed which is decanted from the carmine process. Into this, newly precipitated alumina is put; the mixture is stirred, and heated a little, but not too much. Whenever the alumina has absorbed the color, the mixture is allowed to settle, and the liquor is drawn off.

Sometimes alum is dissolved in the decoction of cochineal, and potash is then added, to throw down the alumina in combination with the coloring matter; but in this way an indifferent pigment is obtained. Occasionally, solution of tin is added, to brighten the dye.

A lake may be obtained from kermes, in the same way as from cochineal; but now it is seldom had recourse to.

Brazil-wood lakes.—Brazil wood is to be boiled in a proper quantity of water for 15 minutes; then, alum and solution of tin being added, the liquor is to be filtered, and a solution of potash poured in as long as it occasions a precipitate. This is separated by

the filter, washed in pure water, mixed with a little gum water, and made into cakes. Or, the Brazil wood may be boiled along with a little vinegar, the decoction filtered, alum and salt of tin added, and then potash-ley poured in to precipitate the lake. For 1 pound of Brazil wood, 30 to 40 pounds of water, and from $1\frac{1}{2}$ to 2 pounds of alum, may be taken, in producing a deep red lake; or the same proportions with half a pound of solution of tin. If the potash be added in excess, the tint will become violet. Cream of tartar occasions a brownish cast.

Madder lake.—A fine lake may be obtained from madder, by washing it in cold water as long as it gives out color; then sprinkling some solution of tin over it, and setting it aside for some days. A gentle heat may also be applied. The red liquor must be then separated by the filter, and decomposed by the addition of carbonate of soda, when a fine red precipitate will be obtained. Or, the reddish brown coloring matter of a decoction of madder may be first separated by acetate of lead, and then the rose-red color with alum. Or, madder tied up in a bag is boiled in water; to the decoction, alum is added, and then potash. The precipitate should be washed with boiling water, till it ceases to tinge it yellow; and it is then to be dried.

The following process merits a preference:

Diffuse 2 pounds of ground madder in 4 quarts of water, and after a maceration of 10 minutes, strain and squeeze the grounds in a press. Repeat this maceration, &c. twice upon the same portion of madder. It will now have a fine rose color. It must then be mixed with 5 or 6 pounds of water and half a pound of bruised alum, and heated upon a water bath for 3 or 4 hours, with the addition of water, as it evaporates, after which the whole must be thrown upon a filter cloth. The liquor which passes is to be filtered through paper, and then precipitated by carbonate of potash. If the potash be added in three successive doses, three different lakes will be obtained, of successively diminishing beauty. The precipitates must be washed till the water comes off colorless.

Blue lakes are hardly ever prepared, as indigo, Prussian blue, cobalt blue, and ultramarine, answer every purpose of blue pigments.

Green lakes are made by a mixture of yellow lakes with blue pigments; but chrome yellows mixed with blues produce almost all the requisite shades of green.

LAMINABLE is said of a metal which may be extended by passing between steel or hardened (chilled) cast-iron rollers.

For a description of metal rolling presses, see IRON and MINT; and

For a table of the relative laminability of metals, see DUCTILITY.

LAMIUM ALBUM, or the dead nettle, is said by Leuchs to afford in its leaves a greenish-yellow dye. The *L. purpureum* dyes a reddish-gray with salt of tin, and a greenish tint with iron liquor.

LAMPS differ so much in principle, form, and construction, as to render their description impossible, as a general subject of manufacture. In fact, the operations of the lampist, like those of the blacksmith, cabinet-maker, cooper, coppersmith, tinman, turner, &c., belong to a treatise upon handicraft trades. I shall here, however, introduce a tabular view of the relative light and economy of the lamps most generally known.

Kind of Lamps.	Intensity of light during						Mean of 7 hours.	Consumption per hour in grammes.	Light from 100 parts of oil.
	1 hour	2 hours	3 hours	4 hours	5 hours	6 hours			
1. Mechanical lamp of Carcel -							100	42	238
2. Fountain lamp, and a chimney with flat wick -	100	98	98	97	96	96	125	11	113
3. Dome argand -	103	90	72	61	42	34	31	26.714	116
4. Sinumbra lamp -	102	95	83	81	78	66	56	37.145	150
5. Do. with fountain above -	100	90	70	52	41	32	85	43	197
6. Do. with another beak -	100	97	95	92	89	86	41	18	227
7. Girard's hydrostatic lamp -	101	96	84	81	76	70	63.66	34.714	182
8. Thilorier's or Parker's hydrostatic lamp -	106	103	100	94	92	90	107.66	51.143	215

In the above table, for the purpose of comparing the successive degrees of intensity 100 represents the mean intensity of light during the first hour. The quantity of oil consumed per hour is given in grammes, of $15\frac{1}{2}$ grains each. The last column expresses the quantity of light produced with a like consumption of oil, which was in all cases 100 grammes. See CANDLES.

The following table of M. Peclet is perhaps more instructive:—

Nature of the light.	Intensity.	Consumption per hour in grammes.	Cost		Fat producing the same light.	Cost per hour.
			per kilo-gramme.	of light per hour.		
			<i>francs.</i>	<i>cents.</i>	<i>grammes.</i>	<i>cents.</i>
1. Mechanical lamp -	100	42	1.40	5.8	42	5.8
2. Flat-wick mechan. do.	12.05	11	1.40	1.5	88	12.3
3. Hemispherical dome lamp - - -	31.0	26.714	1.40	3.7	86.16	12.0
4. Sinumbra lamp -	85	43	1.40	6.0	50.58	7.0
5. Do. with a lateral fountain or vase -	41	18	1.40	2.5	43.90	6.1
6. Do. with a fountain above - - -	90	43	1.40	6.0	47.77	6.6
7. Girard's hydrostatic lamp - - -	63.66	34.71	1.40	4.8	54.52	7.6
8. Thilorier's or Parker's lamp - - -	107.66	51.143	1.40	7.1	47.5	6.6
9. Candle, 6 in lb. -	10.66	8.51	1.40	1.2	70.35	9.8
10. Do. 8 in lb. -	8.74	7.51	1.40	1.0	85.92	12.0
11. Do. 6 with smaller wick - - -	7.50	7.42	2.40	1.7	98.93	23.7
12. Wax candle, 5 in lb.	13.61	8.71	7.60	5.7	64.04	48.6
13. Sperm candle, do.	14.40	8.92	7.60	5.8	61.94	47.8
14. Stearine candle, do.	14.30	9.35	6.00	5.5	65.24	37.1
15. Coal gas - - -	127	136 litres		5.0	107 litres	3.9
16. Oil gas - - -	127	136 do.		5.0	30	3.9

The light of the mechanical lamp is greatly over-rated relatively to that of gas. The cost of the former is at least 10 times greater than of the latter, in London.

The leading novelty under this title, is the construction of lamps for burning spirits of turpentine, in the place of the fat oils which alone have been in use from the most remote ages down to the present time. Several patents have recently been obtained for these lamps, under the fantastic title of *Camphine*; one by Mr. William Young, and another by Messrs. Rayner and Carter, as the invention of a working miner—Roberts. Having been employed by the proprietors of these patents to examine the performances of their respective lamps, I here insert the two reports drawn up by me on these occasions:—

"The *Vesta Lamp*, burning with its utmost brilliancy, without smoke, emits a light equal to very nearly twelve wax or sperm candles of three or four to the pound; and in so doing, it consumes exactly one imperial pint of spirits of turpentine (value sixpence retail) in ten hours; hence the cost per hour for a light equal to ten such candles is one halfpenny; whereas that from wax candles would be nearly sixpence; from spermaceti ditto, fivepence; from stearine ditto, fourpence; from Palmer's spreading wick ditto, nearly threepence; from tallow moulds, $2\frac{1}{2}d$; from sperm oil in Carcel's Mechanical French Lamp, $1\frac{1}{2}d$.

"One peculiar advantage of the *Vesta Lamp* is the snowy whiteness of its light, which is such as to display the more delicate colors of natural and artificial objects, flowers, paintings, &c., in their true tints, instead of the degraded hues visible by the light of candles and ordinary oil lamps.

"The size of the flame from which so much light is emitted in the *Vesta Lamp*, is greatly smaller than that of oil or gas Argand flames of equal intensity; a circumstance to be accounted for from the difference in chemical composition between spirits of turpentine and fat oils. The spirits consist entirely of carbon and hydrogen; in the proportion of $88\frac{1}{2}$ of the former element, and $11\frac{1}{2}$ of the latter, in 100 parts; and they consume 328 parts of oxygen; whereas sperm and other unctuous oils consist of 78 parts of carbon, $11\frac{1}{2}$ of hydrogen, and $10\frac{1}{2}$ of oxygen, in 100 parts; and these consume only

287·2 of oxygen, in being burnt; because the oxygen already present in the oil neutralizes 2·6 parts of the carbon and 0·4 of the hydrogen, thus leaving only 85½ parts of the combustible elements for the atmosphere to burn. For this reason, 87½ parts by weight of spirits of turpentine, will consume as much oxygen as 100 parts of sperm oil; and will afford, moreover, a more vivid light, because they contain no oxide, as fat oils do, which serves to damp the combustion. In the spirits of turpentine, the affinity of its elements for oxygen is entire, whereas in fat oil the affinity is partially neutralized by the oxides it contains; somewhat as the flame of spirits of wine is weakened by their dilution with water.

"Among the many applications of science to the useful arts, for which the present age is so honorably distinguished, few are more meritorious than the Camphine lamps, by which we can produce a snow-white flame from the cleanly, colorless spirits of turpentine—a pure combustible fluid, in place of the smeary rank oils which contain a seventh part of incombustible matter. Being so rich in hydro-carbon, the spirits require peculiar artifices for complete consumption and the development of their full power of yielding light without smoke or smell. This point of perfection seems to be happily attained by the invention of the two parallel flat rings in the Paragon lamp, a larger and smaller, forming a cone round the margin of the wick, which cause a rapid reverberation of the air against the flame: thus consuming every particle of volatilized vapor, and adding energy to the luminous undulations. Hence the patent Paragon lamp in full action emits a light equal to that of sixteen wax-candles, three to the pound, but of better quality, approaching in purity to that of the sun-beam,—therefore capable of displaying natural and artificial objects in their true colors. But these lamps are very apt to smoke.

"One imperial pint of rectified spirits of turpentine, value 6d. retail, will burn for twelve hours in this lamp, affording all the time the illumination of eleven wax-candles.

"The Paragon Camphine lamp is attended with no danger in use.

"The Cost, as compared with other Lamps or Candles, is as follows: viz.—

	PER HOUR.
Paragon Camphine Lamp (equal to 11 wax candles), less than One Halfpenny.	
Wax Candles - - - - -	6½d.
Spermaceti ditto - - - - -	5½
Adamantean Wax (Stearic Acid) - - - - -	4½
Palmer's Spread-Wick Candles - - - - -	3½
Cocoa Nut Candles - - - - -	4½
Moulds (Tallow) - - - - -	2½
Carcel's Lamp, with Sperm oil - - - - -	2"

See ILLUMINATION, COST OF, for a description of an excellent oil lamp.

LAMP OF DAVY consists of a common oil lamp, surmounted with a covered cylinder of wire gauze, for transmitting light to the miner without endangering the kindling of the atmosphere of fire-damp which may surround him; because carbureted hydrogen, in passing through the meshes of the cylindric cover, gets cooled by the conducting power of the metallic gauze, below the point of its accension.

The apertures in the gauze should not be more than 1-20th of an inch square. Since the fire damp is not inflamed by ignited wire, the thickness of the wire is not of importance, but wire from 1-40th to 1-60th of an inch in diameter is the most convenient.

The cage or cylinder should be made by double joinings, the gauze being folded over in such a manner as to leave no apertures. When it is cylindrical, it should not be more than two inches in diameter; because in larger cylinders, the combustion of the fire-damp renders the top inconveniently hot; a double top is always

a proper precaution, fixed $\frac{1}{2}$ or $\frac{3}{4}$ of an inch above the first top. See fig. 839.

The gauze cylinder should be fastened to the lamp by a screw *b*, fig. 840, of four or five turns, and fitted to the screw by a tight ring. All joinings in the lamp should be made with hard solder; as the security depends upon the circumstance that no aperture exists in the apparatus larger than in the wire-gauze.

The parts of the lamp are,

1. The brass cistern *a*, *d*, *fig.* 840, which contains the oil. It is pierced at one side of the centre with a vertical narrow tube, nearly filled with a wire which is recurved above, at the level of the burner, to trim the wick, by acting on the lower end of the wire *e* with the fingers. It is called the safety-trimmer.

2. The rim *b* is the screw neck for fixing on the gauze cylinder, in which the wire-gauze cover is fixed, and which is fastened to the cistern by a screw fitted to *b*.

3. An aperture *c* for supplying oil. It is fitted with a screw or a cork, and communicates with the bottom of the cistern by a tube at *f*. A central aperture for the wick.

4. The wire-gauze cylinder, *fig.* 839, which should not have less than 625 apertures to the square inch.

5. The second top, $\frac{3}{4}$ of an inch above the first, surmounted by a brass or copper plate, to which the ring of suspension may be fixed. It is covered with a wire cap in the figure.

6. Four or six thick vertical wires, *g' g' g' g'*, joining the cistern below with the top plate, and serving as protecting pillars round the cage. *g* is a screw-pin to fix the cover, so that it shall not become loosened by accident or carelessness. The oil-cistern *fig.* 840 is drawn upon a larger scale than *fig.* 839, to show its minuter parts.

When the wire-gauze safe-lamp is lighted and introduced into an atmosphere gradually mixed with fire-damp, the first effect of the fire-damp is to increase the length and size of the flame. When the inflammable gas forms so much as 1-12th of the volume of the air, the cylinder becomes filled with a feeble blue flame, while the flame of the wick appears burning brightly within the blue flame. The light of the wick augments till the fire-damp increases to 1-6th or 1-5th, when it is lost in the flame of the fire-damp, which in this case fills the cylinder with a pretty strong light. As long as any explosive mixture of gas exists in contact with the lamp, so long it will give light; and when it is extinguished, which happens whenever the foul air constitutes so much as 1-3d of the volume of the atmosphere, the air is no longer proper for respiration; for though animal life will continue where flame is extinguished, yet it is always with suffering. By fixing a coil of platinum wire above the wick, ignition may be maintained in the metal when the lamp itself is extinguished; and from this ignited wire the wick may be again rekindled, on carrying it into a less inflammable atmosphere.

"We have frequently used the lamps where the explosive mixture was so high as to heat the wire-gauze red-hot; but on examining a lamp which has been in constant use for three months, and occasionally subjected to this degree of heat, I cannot perceive that the gauze cylinder of iron wire is at all impaired. I have not, however, thought it prudent, in our present state of experience, to persist in using the lamps under such circumstances, because I have observed, that in such situations the particles of coal dust floating in the air, fire at the gas burning within the cylinder, and fly off in small luminous sparks. This appearance, I must confess, alarmed me in the first instance, but experience soon proved that it was not dangerous.

"Besides the facilities afforded by this invention to the working of coal-mines abounding in fire-damp, it has enabled the directors and superintendents to ascertain, with the utmost precision and expedition, both the presence, the quantity, and correct situation of the gas. Instead of creeping inch by inch with a candle, as is usual, along the galleries of a mine suspected to contain fire-damp, in order to ascertain its presence, we walk firmly on with the safe-lamps, and, with the utmost confidence, prove the actual state of the mine. By observing attentively the several appearances upon the flame of the lamp, in an examination of this kind, the cause of accidents which happened to the most experienced and cautious miners is completely developed; and this has hitherto been in a great measure matter of mere conjecture.

"It is not necessary that I should enlarge upon the national advantages which must necessarily result from an invention calculated to prolong our supply of mineral coal, because I think them obvious to every reflecting mind; but I cannot conclude without expressing my highest sentiments of admiration for those talents which have developed the properties, and controlled the power, of one of the most dangerous elements which human enterprise has hitherto had to encounter."—See Letter to Sir H. Davy, in *Journal of Science*, vol. i. p. 302, by John Buddle, Esq., generally and justly esteemed one of the most scientific coal-miners in the kingdom.

Mr. Buddle, in a letter dated 21st August, 1835, which is published in Dr. Davy's life of his brother Sir Humphrey, says:—

"In the evidence given in my last examination before a committee of the House of Commons, I stated that after nearly twenty years' experience of 'the Davy' with from 1000 to 1500 lamps in daily use, in all the variety of circumstances incidental to coal mining, without a single accident having happened which could be attributed to

a defect in its principle, or even in the rules for its practical application, as laid down by Sir Humphrey—I maintained that 'the Davy' approximated perfection, as nearly as any instrument of human invention could be expected to do. We have ascertained distinctly that the late explosion did not happen in that part of the mine where the Davys were used. They were all found in a perfect state after the accident—many of them in the hands of the dead bodies of the sufferers."

LAMP-BLACK. See BLACK.

LAMPATES and LAMPIC ACID. When a spirit of wine lamp has its cotton wick surmounted with a spiral coil of platinum wire, after lighting it for a little, it may be blown out, without ceasing to burn the alcohol; for the coil continues ignited, and a current of hot vapor continues to rise, as long as the spirit lasts. This vapor was first condensed and examined by Professor Daniell, who called it lampic acid. It has a peculiar, strongly acid, burning taste, and a spec. grav. of 1.015. It possesses in an eminent degree the property of reducing certain metallic solutions; such as those of platinum, gold, and silver. The lampates may be prepared by saturating the above acid with the alkaline and earthy carbonates.

LAPIDARY, *Art of*. The art of the lapidary, or that of cutting, polishing, and engraving gems, was known to the ancients, many of whom have left admirable specimens of their skill. The Greeks were passionate lovers of rings and engraved stones; and the most parsimonious among the higher classes of the Cyrenians are said to have worn rings of the value of ten minæ (about 30*l*. of our money.) By far the greater part of the antique gems that have reached modern times, may be considered as so many models for forming the taste of the student of the fine arts, and for inspiring his mind with correct ideas of what is truly beautiful. With the cutting of the diamond, however, the ancients were unacquainted, and hence they wore it in its natural state. Even in the middle ages, this art was still unknown; for the four large diamonds which enrich the clasp of the imperial mantle of Charlemagne, as now preserved in Paris, are uncut, octahedral crystals. But the art of working diamonds was probably known in Hindostan and China, in very remote periods. After Louis de Berghen's discovery, in 1476, of polishing two diamonds by their mutual attrition, all the finest diamonds were sent to Holland to be cut and polished by the Dutch artists, who long retained a superiority, now no longer admitted by the lapidaries of London and Paris.

The operation of gem cutting is abridged by two methods; 1. by cleavage; 2. by cutting off slices with a fine wire, coated with diamond powder, and fixed in the stock of a hand-saw. Diamond is the only precious stone which is cut and polished with diamond powder, soaked with olive oil, upon a mill plate of very soft steel.

Oriental rubies, sapphires, and topazes, are cut with diamond powder soaked with olive oil, on a copper wheel. The facets thus formed are afterwards polished on another copper wheel, with tripoli, tempered with water.

Emeralds, hyacinths, amethysts, garnets, agates, and other softer stones, are cut at a lead wheel, with emery and water; and are polished on a tin wheel with tripoli and water, or, still better, on a zinc wheel, with putty of tin and water.

The more tender precious stones, and even the pastes, are cut on a mill-wheel of hard wood, with emery and water; and are polished with tripoli and water, on another wheel of hard wood.

Since the lapidary employs always the same tools, whatever be the stone which he cuts or polishes, and since the wheel discs alone vary, as also the substance he uses with them, we shall describe, first of all, his apparatus, and then the manipulations for diamond-cutting, which are applicable to every species of stone.

The lapidary's mill, or wheel, is shown in perspective in fig. 841. It consists of

841

(see fig. 842), joined solidly by mortises

a strong frame made of oak carpentry, with tenon and mortised joints, bound together with strong bolts and screw nuts. Its form is a parallelopiped of from 8 to 9 feet long, by from 6 to 7 high; and about 2 feet broad. These dimensions are large enough to contain two cutting wheels alongside of each other, as represented in the figure.

Besides the two sole bars *a* *b*, we perceive in the breadth, 5 cross bars, *c*, *d*, *e*, *f*, *g*. The two extreme bars *c* and *g*, are a part of the frame-work, and serve to bind it. The two cross-bars *d* and *f*, carry each in the middle of their length, a piece of wood as thick as themselves, but only $4\frac{1}{2}$ inches long and tenons with that cross bar, as well as

with the one placed opposite on the other parallel face. These two pieces are called *summers* (lintels); the one placed at *v* is the upper; the one at *r*, the lower.

In *fig. 842* this face is shown inside, in order to explain how the mill wheel is placed and supported. The same letters point out the same objects, both in the preceding and the following figures.

In each of these *summers* a square hole is cut out, exactly opposite to the other; in which are adjusted by friction, a square piece of oak *a, a*, *fig. 842*, whose extremities are perforated with a conical hole, which receives the two ends of the arbor *h* of the wheel *i*, and forms its socket. The square bar is adjusted at a convenient height, by a double wooden wedge *b b*.

The cross bar in the middle *e* supports the table *c c*, a strong plank of oak. It is pierced with two large holes whose centres coincide with the centre of the conical holes hollowed out at the end of the square pins. These holes, of about 6 inches diameter each, are intended to let the arbor pass freely through, bearing its respective wheel. (See one of these holes at *i*, in *fig. 846* below.)

Each wheel is composed of an iron arbor *h*, *fig. 843*, of a grinding-wheel *i*, which differs in substance according to circumstances, as already stated, and of the pulley *j*, furnished with several grooves (see *fig. 844*), which has a square fit upon the arbor. The arbor carries a collet *d*, on which are 4 iron pegs or pins that enter into the wheel to fasten it.

The wheel plate, of which the ground plan is shown at *k*, is hollowed out towards its centre to half its thickness; when it is in its position on the arbor, as indicated in *fig. 844*, a washer or ferrule of wrought iron is put over it, and secured in its place by a double wedge. In *fig. 844* the wheel-plate is represented in section, that the connexion of the whole parts may be seen.

A board *g* (see *fig. 841* and *fig. 849*), about $7\frac{1}{2}$ inches high, is fixed to the part of the frame opposite to the side at which the lapidary works, and it prevents the substances made use of in the cutting and polishing, from being thrown to a distance by the centrifugal force of the wheel-plate.

Behind this apparatus is mounted for each grinding-plate, a large wheel *l* (see *fig. 841*), similar to a cutter's, but placed horizontally. This wheel is grooved round its circumference to receive an endless cord or band, which passes round one of the grooves of the pulley *j*, fixed below the wheel-plate. Hence, on turning the fly-wheel *l*, the plate revolves with a velocity relative to the velocity communicated to the wheel *l*, and to the difference of diameter of the wheel *l* and the pulley *j*. Each wheel *l*, is mounted on an iron arbor, with a crank (see *m*, *fig. 845*.)

The lower pivot of that arbor *h* is conical, and turns in a socket fixed in the floor. The great wheel *l* rests on the collet *i*, furnished with its 4 iron pins, for securing the connexion. Above the wheel an iron washer is laid, and the whole is fixed by a double wedge, which enters into the mortise *l*, *fig. 845*.

Fig. 846 exhibits a ground-plan view of all this assemblage of parts, to explain the structure of the machine. Every thing that stands above the upper *summer-bar* has been suppressed in this representation. Here we see the table *c c*; the upper *summer* *m*; the one wheel-plate *l*, the other having been removed to show that the endless cord does not cross; the two large wheels *l, l*, present in each machine, the crank bar *n*, seen separate in *fig. 847*, which serves for turning the wheel *l*.

This bar is formed of 3 iron plates, *n, o; p, q; and q, r*; (*fig. 847*.) The first is

bent round at the point *n*, to embrace the stud *s*; the second, *p q*, is of the same breadth and thickness as the first; and the third is adjusted to the latter with a hinge joint, at the point *q*, where they are both turned into a circular form, to embrace the crank *m*. When all these pieces are connected, they are fixed at the proper lengths by the buckles or square rings *t t t*, which embrace these pieces as is shown in *fig. 846*.

The stud *s*, seen in *fig. 847*, is fixed to the point *v* by a wedge key upon the arm *p*, represented separately, and in perspective in *fig. 848*. The laborer seizing the two upright pegs or handles *x x*, by the alternate forward and backward motion of his arm, he communicates the same motion to the crank rod, which transmits it to the crank of the arbor *m*, and impresses on that arbor, and the wheel which it bears, a rotatory movement.

Fig. 849, shows piece-meal and in perspective, a part of the lapidary's wheel-mill. There we see the table *c c*, the grind-plate *i*, whose axis is kept in a vertical position by the two square plugs *a a*, fixed into the two *summers* by the wedges *b b*. On the two sides of the wheel-plate we perceive an important instrument called a *dial*, which serves to hold the stone during the cutting and polishing. This instrument has received lately important ameliorations, to be described in *fig. 850*. The lapidary holds this instrument in his hand, he rests it upon the iron pins *u u* fixed in the table, lest he should be affected by the velocity of the revolving wheel-plate. He loads it sometimes with weights *e, e*, to make it take better hold of the grinding plate.

One of the most expert lapidaries of Geneva works by means of the following improved mechanism, of his own invention, whereby he cuts and polishes the facets with extreme regularity, converting it into a true dial.

Fig. 850 shows this improvement. Each of the two jaws bears a large conchoidal cavity, into which is fitted a brass ball, which carries on its upper part a tube *e*, to whose extremity is fixed a dial-plate *f f*, engraved with several concentric circles, divided into equal parts, like the toothed-wheel cutting engine-plate, according to the number of facets to be placed in each cutting range. The tube receives with moderate friction the handle of the cement rod, which is fixed at the proper point by a thumb-screw, not shown in the figure, being concealed by the vertical limb *d*, about to be described.

A needle or index *g*, placed with a square fit on the tail of the cement rod, marks by its point the divisions on the dial-plate *f f*. On the side *m n* of the jaw *a*, there is fixed by two screws, a limb *d*, forming a quadrant whose centre is supposed to be at the centre of the ball. This quadrant is divided as usual into 90 degrees, whose highest point is marked 0, and the lowest would mark about 70; for the remainder of the arc down to 90 is concealed by the jaw. The two graduated plates are used as follows:—

When the cement rod conceals zero or 0 of the limb, it is then vertical, and serves to cut the table of the brilliant; or the point opposite to it, and parallel to the table. On making it slope a little, 5 degrees for example, all the facets will now lie in the same zone, provided that the inclination be not allowed to vary. On turning round the cement rod the index *g* marks the divisions, so that by operating on the circle with 16 divisions, stopping for some time at each, 16 facets will have been formed, of perfect equality, and at equal distances, as soon as the revolution is completed.

Diamonds are cut at the present day in only two modes; into a rose diamond, and a brilliant. We shall therefore confine our attention to these two forms.

The rose diamond is flat beneath, like all weak stones, while the upper face rises into a dome, and is cut into facets. Most usually six facets are put on the central region,

which are in the form of triangles, and unite at their summit; their bases abut upon another range of triangles, which being set in an inverse position to the preceding, present their bases to them, while their summits terminate at the sharp margin of the stone. The latter triangles leave spaces between them which are likewise cut each into two facets. By this distribution the rose diamond is cut into 24 facets; the surface of the diamond being divided into two portions, of which the upper is called the crown, and that forming the contour, beneath the former, is called *dentelle* (lace) by the French artists.

According to Mr. Jeffries, in his Treatise on Diamonds, the regular rose diamond is formed by inscribing a regular octagon in the centre of the table side of the stone, and bordering it by eight right-angled triangles, the bases of which correspond with the sides of the octagon; beyond these is a chain of 8 trapeziums, and another of 16 triangles. The collet side also consists of a minute central octagon, from every angle of which proceeds a ray to the edge of the girdle, forming the whole surface into 8 trapeziums, each of which is again subdivided by a salient angle (whose apex touches the girdle) into one irregular pentagon and two triangles.

To fashion a rough diamond into a brilliant, the first step is to modify the faces of the original octahedron, so that the plane formed by the junction of the two pyramids shall be an exact square, and the axis of the crystal precisely twice the length of one of the sides of the square. The octahedron being thus rectified, a section is to be made parallel to the common base or girdle, so as to cut off 5 eightieths of the whole height from the upper pyramid, and 1 eighteenth from the lower one. The superior and larger plane thus produced is called the *table*, and the inferior and smaller one is called the *collet*; in this state it is termed a *complete square table diamond*. To convert it into a brilliant, two triangular facets are placed on each side of the table, thus changing it from a square to an octagon; a lozenge-shaped facet is also placed at each of the four corners of the table, and another lozenge extending lengthwise along the whole of each side of the original square of the table, which with two triangular facets set on the base of each lozenge, completes the whole number of facets on the table side of the diamond; viz., 8 lozenges, and 24 triangles. On the collet side are formed 4 irregular pentagons, alternating with as many irregular lozenges radiating from the collet as a centre, and bordered by 16 triangular facets adjoining the girdle. The brilliant being thus completed, is set with the table side uppermost, and the collet side implanted in the cavity made to receive the diamond. The brilliant is always three times as thick as the rose diamond. In France, the thickness of the brilliant is set off into two unequal portions; one third is reserved for the upper part or table of the diamond, and the remaining two thirds for the lower part or collet (*culasse*). The table has eight planes, and its circumference is cut into facets, of which some are triangles, and others lozenges. The collet is also cut into facets called *pavillons*. It is of consequence that the pavillons lie in the same order as the upper facets, and that they correspond to each other, so that the symmetry be perfect, for otherwise the play of the light would be false.

Although the rose-diamond projects bright beams of light in more extensive proportion than the brilliant, yet the latter shows an incomparably greater play, from the difference of its cutting. In executing this, there are formed 32 faces of different figures, and inclined at different angles all round the table, on the upper side of the stone. On the collet (*culasse*) 24 other faces are made round a small table, which converts the culasse into a truncated pyramid. These 24 facets, like the 32 above, are differently inclined and present different figures. It is essential that the faces of the top and the bottom correspond together in sufficiently exact proportions to multiply the reflections and refractions, so as to produce the colors of the prismatic spectrum.

The other precious stones, as well as their artificial imitations, called *pastes*, are cut in the same fashion as the brilliant; the only difference consists in the matter constituting the wheel plates, and the grinding and polishing powders as already stated.

In cutting the stones, they are mounted on the cement-rod *n*, fig. 851, whose stem is set upright in a socket placed in the middle of a sole piece at *a*, which receives the stem of the cement-rod. The head of the rod fills the cup of *a*. A melted alloy of tin and lead is poured into the head of the cement-rod, into the middle of which the stone is immediately plunged; and whenever the solder has become solid, a portion of it is pared off from the top of the diamond, to give the pyramidal form shown in the figure at *b*.

There is an instrument employed by the steel polishers for pieces of clock work, and by the manufacturers of watch-glasses for polishing their edges. It consists of a solid oaken table, fig. 852. The top is perforated with two holes, one for passing through the pulley and the arbor of the wheel-plate *n*, made either of lead or of hard

wood, according to circumstances; and the other c for receiving the upper part of the arbor of the large pulley d. The upper pulley of the wheel plate is supported by an iron prop x, fixed to the table by two wooden screws. The inferior pivots of the two pieces are supported by screw-sockets, working in an iron screw-nut sunk into the summer-bar r. The legs of the table are made longer or shorter, according as the workman chooses to stand or sit at his employment. Emery with oil is used for grinding down, and tin-putty or colcothar for polishing. The workman lays the piece on the flat of the wheel-plate with one hand, and presses it down with a lump of cork, while he turns round the handle with the other hand.

The *Sapphire*, *Ruby*, *Oriental Amethyst*, *Oriental Emerald*, and *Oriental Topaz*, are gems next in value and hardness to diamond; and they all consist of nearly pure alumina or clay, with a minute portion of iron as the coloring matter. The following analyses show the affinity in composition of the most precious bodies with others in little relative estimation.

	Sapphire.	Corundum Stone.	Emery.
Alumina or clay - - -	98.5	89.50	86.0
Silica - - -	0.0	5.50	3.0
Oxyde of iron - - -	1.0	1.25	4.0
Lime - - -	0.5	0.00	0.0
	100.0	96.25	93.0

Salamstone is a variety which consists of small transparent crystals, generally six-sided prisms, of pale reddish and bluish colors. The corundum of Battagammana is frequently found in large six-sided prisms: it is commonly of a brown color, whence it is called by the natives *curundu gallé*, cinnamon stone. The hair-brown and reddish-brown crystals are called adamantine spar. Sapphire and salamstone are chiefly met with in secondary repositories, as in the sand of rivers, &c., accompanied by crystals and grains of octahedral iron-ore and of several species of gems. Corundum is found in imbedded crystals in a rock, consisting of indianite. Adamantine spar occurs in a sort of granite.

The finest varieties of sapphire come from Pegu, where they occur in the Capelan mountains near Syrian. Some have been found also at Hohenstein in Saxony, Bilin in Bohemia, Puy in France, and in several other countries. The red variety, the ruby, is most highly valued. Its color is between a bright scarlet and crimson. A perfect ruby above $3\frac{1}{2}$ carats is more valuable than a diamond of the same weight. If it weigh 1 carat, it is worth 10 guineas; 2 carats, 40 guineas; 3 carats, 150 guineas; 6 carats, above 1000 guineas. A deep colored ruby, exceeding 20 carats in weight, is generally called a carbuncle; of which 108 were said to be in the throne of the Great Mogul, weighing from 100 to 200 carats each; but this statement is probably incorrect. The largest oriental ruby known to be in the world was brought from China to Prince Gargarin, governor of Siberia. It came afterwards into the possession of Prince Menzikoff, and constitutes now a jewel in the imperial crown of Russia.

A good blue sapphire of 10 carats is valued at 50 guineas. If it weighs 20 carats, its value is 200 guineas; but under 10 carats, the price may be estimated by multiplying the square of its weight in carats into half a guinea; thus, one of 4 carats would be worth $4^2 \times \frac{1}{2} \text{ G.} = 8 \text{ guineas}$. It has been said that the blue sapphire is superior in hardness to the red, but this is probably a mistake arising from confounding the corundum ruby with the spinelle ruby. A sapphire of a barbel blue color, weighing 6 carats, was disposed of in Paris by public sale for 70*l.* sterling; and another of an indigo blue, weighing 6 carats and 3 grains, brought 60*l.*; both of which sums much exceed what the preceding rule assigns, from which we may perceive how far fancy may go in such matters. The sapphire of Brazil is merely a blue tourmaline, as its specific gravity and inferior hardness show. White sapphires are sometimes so pure, that when properly cut and polished they have been passed for diamonds.

The yellow and green sapphires are much prized under the names of Oriental topaz and emerald. The specimens which exhibit all these colors associated in one stone are highly valued, as they prove the mineralogical identity of these varieties.

Besides these shades of color, sapphires often emit a beautiful play of colors, or *chatoiement*, when held in different positions relative to the eye or incident light; and some likewise present star-like radiations, whence they are called star-stones or *asterias*; sending forth 6 or even 12 rays, that change their place with the position of the stone. This property, so remarkable in certain blue sapphires, is not, however, peculiar to these gems. It seems to belong to transparent minerals which have a rhomboid for their

nucleus, and arises from the combination of certain circumstances in their cutting and structure. Lapidaries often expose the light-blue variety of sapphire to the action of fire, in order to render it white and more brilliant; but with regard to those found at Expailly, in France, fire deepens their color.

3. *Chrysoberyl*, called by Haüy, Cymophane, and by others, Prismatic corundum, ranks next in hardness to sapphire, being 8.5 on the same scale of estimation. Its specific gravity is 3.754. It usually occurs in rounded pieces about the size of a pea, but it is also found crystallized in many forms, of which 8-sided prisms with 8-sided summits are perhaps the most frequent. Lustre vitreous, color asparagus green, passing into greenish-white and olive-green. It shows a bluish opalescence, a light undulating, as it were, in the stone, when viewed in certain directions; which property constitutes its chief attraction to the jeweller. When polished, it has been sometimes mistaken for a yellow diamond; and from its hardness and lustre is considerably valued. Good specimens of it are very rare. It has been found only in the alluvial deposits of rivers, along with other species of gems. Thus it occurs in Brazil, along with diamonds and prismatic topaz; also in Ceylon. Its constituents are alumina, 68.66; glucina, 16.00; silica, 6.00; protoxide of iron, 4.7; oxide of titanium, 2.66; moisture, 0.66; according to Seybert's analysis of a specimen from Brazil. It is difficultly but perfectly fusible before the blow-pipe, with borax and salt of phosphorus. In composition it differs entirely from sapphire, or the rhombohedral corundum.

4. *Spinelle Ruby*, called Dodecahedral corundum, by some mineralogists, and Balas ruby, by lapidaries. Its hardness is 8. Specific gravity, 3.523. Its fundamental form is the hexahedron, but it occurs crystallized in many secondary forms: octahedrons, tetrahedrons, and rhombohedrons. Fracture, conchoidal; lustre, vitreous; color, red, passing into blue and green, yellow, brown, and black; and sometimes it is nearly white. Red spinelle consists of alumina, 74.5; silica, 15.5; magnesia, 8.25; oxide of iron, 1.5; lime, 0.75. Vauquelin discovered 6.18 per cent. of chromic acid in the red spinelle. The red varieties exposed to heat become black and opaque; on cooling, they appear first green, then almost colorless, but at last resume their red color. *Pleonaste* is a variety which yields a deep green globule with borax.

Crystals of spinelle from Ceylon have been observed imbedded in limestone, mixed with mica, or in rocks containing adularia, which seem to have belonged to a primitive district. Other varieties like the pleonaste occur in the drusy cavities of rocks ejected by Vesuvius. Crystals of it are often found in diluvial and alluvial sand and gravel, along with true sapphires, pyramidal zircon, and other gems; as also with octahedral iron ore, in Ceylon. Blue and pearl-gray varieties occur in Südermannland, in Sweden, imbedded in granular limestone. Pleonaste is met with also in the diluvial sands of Ceylon. Clear and finely colored specimens of spinelle are highly prized as ornamental stones. When the weight of a good spinelle exceeds 4 carats, it is said to be valued at half the price of a diamond of the same weight. M. Brard has seen one at Paris which weighed 215 grains.

5. *Zircon or Hyacinth*. Its fundamental form is an isosceles 4-sided pyramid; and the secondary forms have all a pyramidal character. Fracture, conchoidal, uneven; lustre, more or less perfectly adamantine colors, red, brown, yellow, gray, green, white; which, with the exception of some red tints, are not bright. Hardness, 7.5. Specific gravity, 4.5. Zircon and hyacinth consist, according to Klaproth, of almost exactly the same constituents; namely, zirconia, 70; silica, 25; oxide of iron, 5. In the white zirconia there is less iron and more silica. Before the blowpipe the hyacinth loses its color, but does not melt. The brighter zircons are often worked up into a brilliant form, for ornamenting watch cases. As a gem, hyacinth has no high value. It has been often confounded with other stones, but its very great specific gravity makes it to be readily recognised.

6. *Topaz*. The fundamental form is a scalene 4-sided pyramid; but the secondary forms have a prismatic character; and are frequently observed in oblique 4-sided prisms, acuminate by 4 planes. The lateral planes of the prism are longitudinally striated. Fracture, conchoidal, uneven; lustre, vitreous; colors, white, yellow, green, blue; generally of pale shades. Hardness, 8; specific gravity, 3.5. Prismatic topaz consists, according to Berzelius, of alumina, 57.45; silica, 34.24; fluoric acid, 7.75. In a strong heat the faces of crystallization, but not those of cleavage, are covered with small blisters, which however immediately crack. With borax, it melts slowly into a transparent glass. Its powder colors the tincture of violets green. Those crystals which possess different faces of crystallization on opposite ends, acquire the opposite electricities on being heated. By friction, it acquires positive electricity.

Most perfect crystals of topaz have been found in Siberia, of green, blue, and white colors, along with beryl, in the Uralian and Altai mountains, as also in Kamschatka; in Brazil, where they generally occur in loose crystals, and pebble forms of bright yel-

low colors; and in Muela, in Asia Minor, in pale straw-yellow regular crystals. They are also met with in the granitic detritus of Cairngorm, in Aberdeenshire. The blue varieties are absurdly called *oriental aquamarine*, by lapidaries. If exposed to heat, the Saxon topaz loses its color and becomes white; the deep yellow Brazilian varieties assume a pale pink hue; and are then sometimes mistaken for spinelle, to which, however, they are somewhat inferior in hardness. Topaz is also distinguishable by its double refractive property. Tavernier mentions a topaz, in the possession of the Great Mogul, which weighed 157 carats, and cost 20,000*l.* sterling. There is a specimen in the museum of natural history at Paris which weighs 4 ounces 2 gros.

Topazes are not scarce enough to be much valued by the lapidary.

7. *Emerald* and *Beryl* are described in their alphabetical places. Emerald loses its lustre by candle-light; but as it appears to most advantage when in the company of diamonds, it is frequently surrounded with brilliants, and occasionally with pearls. Beryl is the aquamarine of the jewellers, and has very little estimation among lapidaries.

8. *Garnet*. See this stone in its alphabetical place.

9. *Chrysolite*, called *Peridot*, by Haüy; probably the topaz of the ancients, as our topaz was their chrysolite. It is the softest of the precious stones, being scratched by quartz and the file. It refracts double.

10. *Quartz*, including, as sub-species, *Amethyst*, *Rock-crystal*, *Rose-quartz*, *Prase*, or *Chrysoprase*, and several varieties of *calcedony*, as *Cat's-eye*, *Plasma*, *Chrysoprase*, *Onyx*, *Sardonyx*, &c. Lustre, vitreous, inclining sometimes to resinous; colors, very various; fracture, conchoidal; hardness, 7; specific gravity, 2.69.

11. *Opal*, or uncleavable quartz. Fracture, conchoidal; lustre, vitreous or resinous; colors, white, yellow, red, brown, green, gray. Lively play of light; hardness, 5.5 to 6.5; specific gravity, 2.091. It occurs in small kidney-shaped and stalactitic shapes, and large tuberoso concretions. The phenomena of the play of colors in precious opal has not been satisfactorily explained. It seems to be connected with the regular structure of the mineral. Hydrophane, or *oculus mundi*, is a variety of opal without transparency, but acquiring it when immersed in water, or in any transparent fluid. Precious opal was found by Klaproth to consist of silica, 90; water, 10; which is a very curious combination. Hungary has been long the only locality of precious opal, where it occurs near Caschau, along with common and semi-opal, in a kind of porphyry. Fine varieties have, however, been lately discovered in the Faroe islands; and most beautiful ones, sometimes quite transparent, near Gracias a Dios, in the province of Honduras, America. The red and yellow bright colored varieties of fire-opal are found near Zimapan, in Mexico. Precious opal, when fashioned for a gem, is generally cut with a convex surface; and if large, pure, and exhibiting a bright play of colors, is of considerable value. In modern times, fine opals of moderate bulk have been frequently sold at the price of diamonds of equal size: the Turks being particularly fond of them. The estimation in which opal was held by the ancients is hardly credible. They called it *Paideros*, or Child beautiful as love. Nonius, the Roman senator, preferred banishment to parting with his favorite opal, which was coveted by Mark Antony. Opal which appears quite red when held against the light, is called *girasol* by the French; a name also given to the sapphire or corundum asterias or star-stone.

12. *Turquoise* or *Calaite*. Mineral turquoise occurs massive; fine-grained, impalpable; fracture, conchoidal; color, between a blue and a green, soft, and rather bright; opaque; hardness, 6; spec. grav., 2.83 to 3.0. Its constituents are alumina, 73; oxide of copper, 4.5; oxide of iron, 4; water, 18; according to Dr. John. But by Berzelius, it consists of phosphate of alumina and lime, silica, oxides of copper, and iron, with a little water. It has been found only in the neighborhood of Nichabour in the Khorassan, in Persia; and is very highly prized as an ornamental stone in that country. There is a totally different kind of turquoise, called *bone turquoise*, which seems to be phosphate of lime colored with oxide of copper. When the oriental stone is cut and polished, it forms a pleasing gem of inferior value. *Malachite*, or mountain green, a compact carbonate of copper, has been substituted sometimes for turquoise, but their shades are different. Malachite yields a green streak, and turquoise a white one.

13. *Lapis lazuli* is of little value, on account of its softness.

LAZULITE (Eng. and Fr.; *Lazulith*, Germ.); is a blue vitreous mineral, crystallizing in rhomboidal dodecahedrons; spec. grav. 2.76 to 2.94; scratches glass; affords a little water by calcination; fusible into a white glass; dissolves in acids with loss of color; solution leaves an alkaline residuum, after being treated with carbonate of ammonia, filtered, evaporated, and calcined. It consists of silica, 35.8; alumina, 34.8; soda, 23.2; sulphur, 3.1; carbonate of lime, 3.1. This beautiful stone affords the native *ultramarine* pigment, which was very costly till a mode of making it artificially was lately discovered. See **ULTRAMARINE**.

LEAD. (*Plomb*, Fr.; *Blei*, Germ.) This is one of the metals most anciently known

being mentioned in the books of Moses. It has a gray blue color, with a bright metallic lustre when newly cut, but it becomes soon tarnished and earthy looking in the air. Its texture is close, without perceptible cleavage or appearance of structure; the specific gravity of common lead is 11.352; but of the pure metal, from 11.38 to 11.44. It is very malleable and ductile, but soft and destitute of elasticity; fusible at 612° Fahr. by Crighton, at 634° by Kupfer, and crystallizable on cooling, into octahedrons implanted into each other so as to form an assemblage of four-sided pyramids.

There are four oxydes of lead. 1. The suboxyde, of a grayish-blue color, which forms a kind of crust upon a plate of lead long exposed to the air. It is procured in a perfect state by calcining oxalate of lead in a retort; the dark gray powder which remains, is the pure suboxyde. 2. The protoxyde is obtained by exposing melted lead to the atmosphere, or, more readily, by expelling the acid from the nitrate of lead by heat in a platinum crucible. It is yellow, and was at one time prepared as a pigment by calcining lead; but is now superseded by the chromate of this metal. Litharge is merely this oxyde in the form of small spangles, from having undergone fusion; it is more or less contaminated with iron, copper, and sometimes a little silver. It contains likewise some carbonic acid. The above oxyde consists of 104 of metal, and 8 of oxygen, its prime equivalent being 112, upon the hydrogen scale; and it is the base of all the salts of lead. 3. The plumbeous suroxyde of Berzelius, the sesquioxysde of some British chemists, is the well-known pigment called RED LEAD or *minium*. It consists of 100 parts of metal and 10 of oxygen. 4. The plumbic suroxyde of Berzelius, or the peroxyde of the British chemists, is obtained by putting red lead in chlorine water, or in dilute nitric acid. It is of a dark brown, almost black color, which gives out oxygen when heated, and becomes yellow oxyde. It kindles sulphur when triturated with it. This oxyde is used by the analytical chemist to separate, by condensation, the sulphurous acid existing in a gaseous mixture.

Among the ores of lead some have a metallic aspect; are black in substance, as well as when pulverized; others have a stony appearance, and are variously colored, with usually a vitreous or greasy lustre. The specific gravity of the latter ores is always less than 5. The whole of them, excepting the chloride, become more or less speedily black, with sulphureted hydrogen or with hydrosulphurets; and are easily reduced to the metallic state upon charcoal, with a flux of carbonate of soda, after they have been properly roasted. They diffuse a whitish or yellowish powder over the charcoal, which, according to the manner in which the flame of the blowpipe is directed upon it, becomes yellow or red; thus indicating the two characteristic colors of the oxydes of lead.

We shall not enter here into the controversy concerning the existence of native lead, which has been handled at length by M. Brongniart in the *Dictionnaire des Sciences Naturelles*, article *Plomb*, *Mineralogie*.

The lead ores most interesting to the arts are:—

1. *Galena*, sulphuret of lead. This ore has the metallic lustre of lead with a crystalline structure derivable from the cube. When heated cautiously at the blowpipe it is decomposed, the sulphur flies off, and the lead is left alone in fusion; but if the heat be continued, the colored surface of the charcoal indicates the conversion of the lead into its oxydes. Galena is a compound of lead and sulphur, in equivalent proportions, and therefore consists, in 100 parts, of 86½ of metal, and 13½ of sulphur, with which numbers the analysis of the galena of Clausthal by Westrumb exactly agrees. Its specific gravity, when pure, is 7.56. Its color is blackish gray, without any shade of red, and its powder is black, characters which distinguish it from *blende* or sulphuret of zinc. Its structure in mass is lamellar, passing sometimes into the fibrous or granular, and even compact. It is brittle. The *specular galena*, so called from its brightly polished aspect, is remarkable for forming the *slickensides* of Derbyshire—thin seams, which explode with a loud noise when accidentally scratched in the mine.

The argentiferous galena has in general all the external characters of pure galena. The proportions of silver vary from one fifth part of the whole, as at Tarnowitz, in Silesia, to three parts in ten thousand, as in the ore called by the German miners *Weissgültigerz*; but it must be observed, that whenever this lead ore contains above 5 per cent. of silver, several other metals are associated with it. The mean proportion of silver in galena, or that which makes it be considered practically as an argentiferous ore, because the silver may be profitably extracted, is about two parts in the thousand. See *SILVER*. The above rich silver ores were first observed in the Freyberg mines, called *Himmelsfürst* and *Beschertgluck*, combined with sulphuret of antimony; but they have been noticed since in the Hartz, in Mexico, and several other places.

The antimonial galena (*Bournonite*) exhales at the blowpipe the odor peculiar to antimony, and coats the charcoal with a powder partly white and partly red. It usually contains some arsenic.

2. The *Selenuret of lead* resembles galena, but its tint is bluer. Its chemical characters are the only ones which can be depended on for distinguishing it. At the blowpipe it exhales a very perceptible smell of putrid radishes. Nitric acid liberates the selenium. When heated in a tube, oxyde of selenium of a carmine red rises along with selenic acid, white and deliquescent. The specific gravity of this ore varies from 6.8 to 7.69.

3. *Native minium or red lead* has an earthy aspect, of a lively and nearly pure red color, but sometimes inclining to orange. It occurs pulverulent, and also compact, with a fracture somewhat lamellar. When heated at the blowpipe upon charcoal, it is readily reduced to metallic lead. Its specific gravity varies from 4.6 to 8.9. This ore is rare.

4. *Plomb-gomme*.—This lead ore, as singular in appearance as in composition, is of a dirty brownish or orange-yellow, and occurs under the form of globular or gum-like concretions. It has also the lustre and translucency of gum; with somewhat of a pearly aspect at times. It is harder than fluor spar. It consists of oxyde of lead, 40; alumina, 37; water, 18.8; foreign matters and loss, 4.06; in 100. Hitherto it has been found only at Huelgoet, near Poullaouen, in Brittany, covering with its tears or small concretions the ores of white lead and galena which compose the veins of that lead mine.

5. *White lead, carbonate of lead*.—This ore, in its purest state, is colorless and transparent like glass, with an adamantine lustre. It may be recognised by the following characters:—

Its specific gravity is from 6 to 6.7; it dissolves with more or less ease, and with effervescence, in nitric acid; becomes immediately black by the action of sulphureted hydrogen, and melts on charcoal before the blowpipe into a button of lead. According to Klaproth, the carbonate of Leadhills contains 82 parts of oxyde of lead, and 16 of carbonic acid, in 98 parts. This mineral is tender, scarcely scratches calc-spar, and breaks easily with a wavy conchoidal fracture. It possesses the double refracting property in a very high degree; the double image being very visible on looking through the flat faces of the prismatic crystals. Its crystalline forms are very numerous, and are referrible to the octahedron, and the pyramidal prism.

6. *Vitreous lead, or sulphate of lead*.—This mineral closely resembles carbonate of lead; so that the external characters are inadequate to distinguish the two. But the following are sufficient. When pure, it has the same transparency and lustre. It does not effervesce with nitric acid; it is but feebly blackened by sulphureted hydrogen; it first decrepitates and then melts before the blowpipe into a transparent glass, which becomes milky as it cools. By the combined action of heat and charcoal, it passes first into a red pulverulent oxyde, and then into metallic lead. It consists, according to Klaproth, of 71 oxyde of lead, 25 sulphuric acid, 2 water, and 1 iron. That specimen was from Anglesea; the Wanlockhead mineral is free from iron. The prevailing form of crystallization is the rectangular octahedron, whose angles and edges are variously modified. The sulphato-carbonate, and sulphato tri-carbonate of lead, now called *Leadhillite*, are rare minerals which belong to this head.

7. *Phosphate of lead*.—This, like all the combinations of lead with an acid, exhibits no metallic lustre, but a variety of colors. Before the blowpipe upon charcoal, it melts into a globule externally crystalline, which, by a continuance of the heat, with the addition of iron and boracic acid, affords metallic lead. Its constituents are 80 oxyde of lead, 18 phosphoric acid, and 1.6 muriatic acid, according to Klaproth's analysis of the mineral from Wanlockhead. The constant presence of muriatic acid in the various specimens examined is a remarkable circumstance. The crystalline forms are derived from an obtuse rhomboid. Phosphate of lead is a little harder than white lead; it is easily scratched, and its powder is always gray. Its specific gravity is 6.9. It has a vitreous lustre, somewhat adamantine. Its lamellar texture is not very distinct; its fracture is wavy, and it is easily frangible. The phosphoric and arsenic acids being, according to M. Mitscherlich, isomorphous bodies, may replace each other in chemical combinations in every proportion, so that the phosphate of lead may include any proportion, from the smallest fraction of arsenic acid to the smallest fraction of phosphoric acid, thus graduating indefinitely into arseniate of lead. The yellowish variety indicates, for the most part, the presence of arsenic acid.

8. *Muriate of lead. Horn-lead, or murio-carbonate*.—This ore has a pale yellow color, is reducible to metallic lead by the agency of soda, and is not altered by the hydrosulphurets. At the blowpipe it melts first into a pale yellow transparent globule, with salt of phosphorus and oxyde of copper; and it manifests the presence of muriatic acid by a bluish flame. It is fragile, tender, softer than carbonate of lead, and is sometimes almost colorless, with an adamantine lustre. Spec. grav., 606. Its constituents, according to Berzelius, are lead, 25.84; oxyde of lead, 57.07; carbonate of lead, 6.25; chlorine, 8.84; silica, 1.46; water, 0.54; in 100 parts. The carbonate is an accidental ingredient, not

being in equivalent proportion. Klaproth found chlorine, 13.67; lead, 39.98; oxide of lead, 22.57; carbonate of lead, 23.78.

9. *Arsenate of lead*.—Its color of a pretty pure yellow, bordering slightly on the greenish, and its property of exhaling by the joint action of fire and charcoal a very distinct arsenical odor, are the only characters which distinguish this ore from the phosphate of lead. The form of the arseniate of lead, when it is crystallized, is a prism with six faces, of the same dimensions as that of phosphate of lead. When pure, it is reducible upon charcoal, before the blowpipe, into metallic lead, with the copious exhalation of arsenical fumes; but only in part, and leaving a crystalline globule, when it contains any phosphate of lead. The arseniate of lead is tender, friable, sometimes even pulverulent, and of specific gravity 5.04. That of Johann-Georgenstadt consists, according to Rose, of oxide of lead 77.5; arsenic acid 12.5; phosphoric acid 7.5, and muriatic acid 1.5.

10. *Red lead, or Chromate of lead*.—This mineral is too rare to require consideration in the present work.

11. *Plomb vaquelinite. Chromate of lead and copper*.

12. *Yellow lead. Molybdate of lead*.

13. *Tungstate of lead*.

Having thus enumerated the several species of lead ore, we may remark, that galena is the only one which occurs in sufficiently great masses to become the object of mining and metallurgy. This mineral is found in small quantity among the crystalline primitive rocks, as granite. It is however among the oldest talc-schists and clay slates, that it usually occurs. But galena is much more abundant among the transition rocks, being its principal locality, where it exists in interrupted beds, masses, and more rarely in veins. The blackish transition limestone is of all rocks that which contains most galena; as at Pierreville in Normandy; at Clausthal, Zellerfeldt, and most mines of the Harz; at Fahlun, in Sweden; in Derbyshire and Northumberland, &c. In the transition graywacke of the south of Scotland, the galena mines of Leadhills occur. The galena of the primitive formations contains more silver than that of the calcareous.

The principal lead mines at present worked in the world, are the following: 1. Poullaouen and Huelgöet near Carhaix in France, department of Finisterre, being veins of galena, which traverse a clay slate resting upon granite. They have been known for upwards of three centuries; the workings penetrate to a depth of upwards of 300 yards, and in 1816 furnished 500 tons of lead per annum, out of which 1034 pounds avoirdupois of silver were extracted. 2. At Villeforte and Viallax, department of the Lozère, are galena mines said to produce 100 tons of lead per annum, with 400 kilogrammes of silver (880 lbs. avoird.). 3. At Pezey and Macot, to the east of Moutiers in Savoy, a galena mine exists in talc-schist, which has produced annually 200 tons of lead, and about 600 kilogrammes of silver (1320 lbs. avoird.). 4. The mine of Vedrin, near Namur in the Low Countries, is opened upon a vein of galena, traversing compact limestone of a transition district; it has furnished 200 tons of lead, from which 385 pounds avoird. of silver were extracted. 5. In Saxony the galena mines are so rich in silver as to make the lead be almost overlooked. They are enumerated under silver ores. 6. The lead mines of the Harz have been likewise considered as silver ores. 7. Those of Bleyberg in the Eifel are in the same predicament. 8. The galena mines of Bleyberg and Villach in Carinthia, in compact limestone. 9. In Bohemia, to the south-west of Prague. 10. The mines of Joachimsthal, and Bleystadt, on the southern slope of the Erzgebirge, produce argentiferous galena. 11. There are numerous lead mines in Spain, the most important being in the granite hills of Linarès, upon the southern slope of the Sierra Morena, and in the district of the small town of Canjagar. Sometimes enormous masses of galena are extracted from the mines of Linarès. There are also mines of galena in Catalonia, Grenada, Murcia, and Almeria, the ore of the last locality being generally poor in silver. 12. The lead mines of Sweden are very argentiferous, and worked chiefly with a view to the silver. 13. The lead mines of Daouria are numerous and rich, lying in a transition limestone, which rests on primitive rocks; their lead is neglected on account of the silver.

14. Of all the countries in the world, Great Britain is that which annually produces the greatest quantity of lead. According to M. Villefosse, in his *Richesse Minérale*, published in 1810, we had furnished every year 12,500 tons of lead, whilst all the rest of Europe taken together, did not produce so much; but from more recent documents, that estimate seems to have been too low. Mr. Taylor has rated the total product of the United Kingdom per annum at 31,900 tons, a quantity fully 2½ times greater than the estimate of Villefosse (see Conybeare and Phillips's *Geology*, p. 354). Mr. Taylor distributes this product among the different districts as follows:—

	Tons.
Wales, (Flintshire and Denbighshire) - - - - -	7,500
Scotland, (in transition graywacke) - - - - -	2,800
Durham, Cumberland, and Yorkshire, (in carboniferous lime) - - - - -	19,000
Derbyshire, (probably in carboniferous lime) - - - - -	1,000
Shropshire - - - - -	800
Devon and Cornwall, (transition and primitive rocks) - - - - -	800

Total - - - - - 31,900

We thus see that Cumberland, and the adjacent parts of the counties of Durham and York, furnish of themselves nearly three-fifths of the total product. Derbyshire was formerly much more productive. In Cornwall and Devonshire, the lead ore is found in veins in *killas*, a clay-slate passing into graywacke. In North Wales and the adjacent counties, as well as in Cumberland and Derbyshire, the lead occurs in the carboniferous limestone.

In 1835 the total produced was estimated, by Mr. Taylor, at 46,112 tons; of which 19,626 were furnished by Northumberland, Durham, and Cumberland; the mines of Mr. Beaumont alone, yielding 10,000. In 1847, the total produce was as follows:—

	Lead Ore.	Lead.
	Tons.	Tons.
England - - - - -	59,614½	39,507½
Wales - - - - -	18,147½	12,294
Ireland - - - - -	2,251	1,380
Scotland - - - - -	1,159	822½
Isle of Man - - - - -	2,575	1,699
Total - - - - -	83,747	55,703

The English lead-miners distinguish three different kinds of deposits of lead ore; *rake-veins*, *pipe-veins*, and *flat-veins*. The English word vein corresponds to the French term *filon*; but miners make use of it indifferently in England and France, to indicate all the deposits of this ore, adding an epithet to distinguish the different forms; thus, *rake veins* are true veins in the geological acceptation of the word vein; *pipe-veins* are masses usually very narrow, and of oblong shape, most frequently parallel to the plane of the rocky strata; and *flat-veins* are small beds of ores interposed in the middle of these strata.

Rake-veins are the most common form in which lead ore occurs in Cumberland. They are in general narrower in the sandstone which covers the limestone, than in the calcareous beds. A thickness of less than a foot in the former, becomes suddenly 3 or 4 feet in the latter; in the rich vein of Hudgillburn, the thickness is 17 feet in the *Great limestone*, while it does not exceed 3 feet in the overlying *Watersill* or sandstone. This influence exercised on the veins by the nature of the enclosing rock, is instructive; it determines at the same time almost uniformly their richness in lead ore, an observation similar to what has been made in other countries, especially in the veins of Kongsburg in Norway. The Cumberland veins are constantly richer, the more powerful they are, in the portions which traverse the calcareous rocks, than in the beds of sandstone, and more particularly the schistose rocks. It is rare in the rock called *plate* (a solid slaty clay) for the vein to include any ore; it is commonly filled with a species of potter's earth. The upper calcareous beds are also in general more productive than the lower ones. In most of these mines, the veins were not worked till lately below the fifth calcareous bed (the four-fathom limestone), which is 307 yards beneath the mill-stone grit; and as the first limestone stratum is 108 yards beneath it, it follows that the thickness of the part of the ground where the veins are rich in lead does not in general exceed 200 yards. It appears however that veins have been mined in the neighborhood of Alston Moor, downwards to the eleventh calcareous stratum, or Tyne bottom limestone, which is 418 yards under the millstone-grit of the coal formation, immediately above the whin-sill; and that they have been followed above the first limestone stratum, as high as the grindstone sill, which is only 83 yards below the same stratum of mill-stone grit; so that in the total thickness of the plumbiferous formation there is more than 336 yards. It has been asserted that lead veins have been traced even further down, into the *Memery scar* limestone; but they have not been mined.

The greatest enrichment of a vein takes place commonly in the points where its two sides, being not far asunder, belong to the same rock; and its impoverishment occurs when one side is calcareous and the other a schistose clay. The minerals which most

frequently accompany the galena, are carbonate of lime, fluato of lime, sulphate of baryta, quartz, and pyrites.

The pipe-veins (*amas* in French) are seldom of great length; but some have a considerable width; their composition being somewhat similar to that of the *rake-veins*. They meet commonly in the neighborhood of the two systems, sometimes being in evident communication together; they are occasionally barren; but when a wide pipe-vein is metalliferous, it is said to be very productive.

The *flat veins*, or *strata veins*, seem to be nothing else than expansions of the matter of the vein between the planes of the strata; and contain the same ores as the veins in their vicinity. When they are metalliferous, they are worked along with the adjacent rake vein; and are productive to only a certain distance from that vein, unless they get enriched by crossing a rake vein. Some examples have been adduced of advantageous workings in *flat veins* in the great limestone of Cumberland, particularly in the mines of Coalcleugh and Nenthead. The *rake veins*, however, furnish the greater part of the lead which Cumberland and the adjacent counties send every year into the market. Mr. Forster gives a list of 165 lead mines, which have been formerly, or are now, worked in that district of the kingdom.

The metalliferous limestone occupies, in Derbyshire, a length of about 25 miles from north-west to south-east, under a very variable breadth, which towards the south, amounts to 25 miles. Castleton to the north, Buxton to the north-west, and Matlock to the south-east, lie nearly upon its limits. It is surrounded on almost all sides by the mill-stone grit which covers it, and which is, in its turn, covered by the coal strata. The nature of the rocks beneath the limestone is not known. In Cumberland the metalliferous limestone includes a bed of trap, designated under the name of *whinsill*. In Derbyshire the trap is much more abundant, and it is thrice interposed between the limestone. These two rocks constitute of themselves the whole mineral mass, through a thickness of about 550 yards, measuring from the millstone grit; only in the upper portion, that is near the millstone grit, there is a pretty considerable thickness of argillo-calcareous schists.

Four great bodies or beds of limestone are distinguishable, which alternate with three masses of trap, called toadstone. The lead veins exist in the calcareous strata, but disappear at the limits of the toadstone. It has now been ascertained, however, that they recur in the limestone underneath.

LEAD IN THE EXHIBITION.—Sopwith, Thomas, F. R. S., &c. Allenheads, Northumberland, inventor and producer.

Specimens of lead ores and associated minerals, with examples of the various stages of progress from their being excavated in the mine and carried through the several departments of washing and smelting, until furnished and ready for the market in the form of a cake of silver and a pig or piece of lead known as W. B. lead.

The specimens of minerals usually associated with lead ores are collected from various mines, and are fitted together in a separate case, under the direction of the exhibitor, by Messrs. Cain and Wallace of Nenthead, and others.

The general arrangement of the strata in which these ores and minerals are found is exhibited by a section of part of the lead mining district belonging to Wentworth Blackett Beaumont, Esq., at Allenheads, in the county of Northumberland, and from whose mines the specimens of lead ores and examples of process during conversion into lead and silver are taken; and a further illustration of the geographical structure of this part of England is given by an isometrical plan and section by the exhibitor, showing a considerable tract of mining ground in the manor of Alston Moor, in the county of Cumberland.

The principal phenomena of mineral veins and displacement of the strata in which lead ore is obtained in the north of England are shown by dissected models, invented by the exhibitor, and examples of the finished products are contained in a separate case, from Mr. Beaumont's smelt-mills, under the direction of his agent, Mr. Thomas Steel.

This collection, the general nature of which is here briefly indicated, is intended to illustrate the geological position and usual products of the north of England lead mines.

The following is the order of the five several portions, and which are more particularly described under these several heads in the sequel.

1. Sections of strata at Allenheads and Alston.
2. Models to illustrate mineral veins, &c.
3. Minerals associated with lead ores.
4. Examples of the various stages of progress from the mine to the market.
5. Lead and silver prepared for sale.

1. As the express object of this collection is to afford a general view of the whole of the principal features relative to the extensive and important departments of British industry connected with lead mining, and as this information is more expressly intended for the use of those who are not locally conversant with the physical conditions under

which lead ores are usually obtained, the exhibitor has in the first instance thought it necessary to present clear and distinct views of the geological structure of the districts in which the chief lead mines of the north of England are situated, in order that, without going into purely technical details, which are only of local interest, the several strata and order of superposition may be readily understood.

As an approximate comparative view of the produce, it may be considered that the lead raised in Mr. Beaumont's mines amounts to about one-fourth of the quantity raised in England, about one-sixth of the produce of Great Britain, and about one-tenth of that of the whole of Europe, including the British Isles. They have been extensively worked from time immemorial; part of them are situated in the manors belonging to Mr. Beaumont, in the dales of East and West Allen, in the south-west part of Northumberland, and others are situated in the wild district of moors which forms the western extremity of the county of Durham.

This part of the country happens to be at once the centre of the island of Great Britain, and by far the most elevated part of it which is thickly populated; for, scattered over hills and dales, which present an aspect of verdant cultivation mixed with heathy moors, are to be found some thousands of inhabitants, nearly the whole of them either employed in lead mines or smelting-mills, or indirectly deriving a livelihood from some connection with lead-mining business. Allenheads forms a central position in the midst of these mines; and the agent's house, shown on the section, is exactly 1400 feet above the level of the sea, and is the highest house of its magnitude in Great Britain; nor are many of the cottages of shepherds and other moorland habitations of greater elevation.

The datum or base line of the Allenheads section is 700 feet above the level of the sea. The drawing, 16½ feet in length, is on a true scale of 100 feet to an inch; by a true scale being meant, that the lengths and heights are projected to the scale or proportion, so that a true miniature profile of the country is given, as well as a correct reduction of the relative size of the various rocks. The extent of country thus shown is not quite 4 miles, being 3 miles 1220 yards.

The spectator is supposed to be looking to the north, and the section commences at a point about half a mile eastward from a place called Kilhope Head, which is conspicuously marked in all English maps, inasmuch as the three counties of Northumberland, Durham, and Cumberland all meet in one spot. At about three quarters of a mile from the point of commencement, the section represents the hill called Kilhope Law; it is on the boundary line of the counties of Northumberland and Durham, and is the highest point of land in the last-named county, being 2206 feet above the level of the sea. But out of the limits of this section, and about 10 miles south-west from Kilhope Law, the same strata which are here delineated reach an altitude of 2901 feet above the sea, and this is the highest elevation attained by the rocks which form the carboniferous or mountain limestone of the north of England.

Such being the stratification of the central portion of the narrow part of the island of which the coal fields of the Tyne and Wear form the extremity on the east bordering on the German Ocean, for some distance north and south of Newcastle, while a similar coal field is found at the western extremity near Whitehaven, it may be observed with reference to these coal fields, that they lie over or upon the mountain limestone formation. The coal beds so extensively worked in the Newcastle and Durham coal mines or collieries, gradually rise to the west, and one by one crop out or bassett according to the undulations of the country. At length, at about 20 miles west of the German Sea, the lowest of the coal beds crops out, and from beneath it gradually appear the limestone strata, which continue to rise nearly coincident with the general rise of the country, until they reach the summit of Cross Fell (2901 feet). And this general and very gradual inclination of the strata, a feature of the greatest importance in practical mining, is clearly and accurately delineated in this section.

In a thickness of about 2000 feet of the alternating beds of sandstone, clay, and limestone, which form the strata of the mining districts of Alladale, Alston, and Wear-dale, there is one single stratum of limestone, called the "great limestone," the veins in which have produced nearly, if not quite, as much ore as all the other strata put together. This stratum is delineated on the section, and may be observed lying at a depth of about 850 feet below the summit of Kilhope Law. Somewhat exceeding two miles eastward of this, at Allenheads, the top of the great limestone is 230 feet from the top of a shaft called Gin-Hill Shaft. Its thickness, which is tolerably uniform over several hundred square miles of country, is about 60 feet; and it is from this stratum of limestone that nearly all the specimens in this collection have been obtained.

The dislocations of strata which constitute for the most part important mineral veins, are exhibited more in detail in the series of geological models which form a part of this collection: but some of the great features of displacement may be noticed on the section.

At about a quarter of a mile to the west of, or left hand direction from Kilhope Law, the great limestone, and all other associated beds, are thrown down a depth of about 150 feet for a space of nearly 700 feet; and again, at the distance of nearly a mile from Allenheads, a vast dislocation takes place, by which the great limestone, it will be seen, is brought nearly to the surface, the amount of displacement being about 400 feet. It is in the great limestone that by far the most extensive portion of the workings of Allenheads lead mines are situated, and the galleries drawn on the section convey a general idea of the position of the mines. In a great thickness of strata above the great limestone, only two beds of that rock are found. One of these is called "little limestone." It is from 10 to 12 feet thick, and is 75 feet above the top of the great limestone. The other is still more inconsiderable, being only 3 or 4 feet thick, and is 440 feet above the great limestone. It is remarkable with what exactness this thin bed is found near the summit of hills, the intervening spaces having apparently been removed by denudation; so as to form in one case a gap of $6\frac{1}{2}$ miles, and in another of $1\frac{1}{2}$ miles, in which the Tell Top limestone is entirely cut off.

But beneath the great limestone, as will be seen by the lines of blue color, are several beds of the same description of rock, viz., at distances respectively of 30, 106, 190, 250, and 287 feet, and the thickness 2, 24, 10, 15, and 35 feet. These are known by descriptive local names, and comprise all that are of significance as regards lead-mining operations.

The Allenheads mines being situated for the most part at depths from the surface varying from 200 to 600 feet, are drained, partly by ordinary water-wheels, some of which are shown on the section, and partly by the new hydraulic engines invented by Mr. W. G. Armstrong, and four of which are now used for draining and other mining purposes at Allenheads mines.

Examples of the various Stages of Progress from the Mine to the Market.—This part of the collection is arranged in five cases, each containing six boxes of one square foot each, being in all thirty boxes.

Fifteen of these boxes, in a line furthest from the front edge of the counter, contain specimens of lead-mining from the excavation of the ore in the mine, and showing the several stages of progress until ready to send to the smelt mill; and the other fifteen boxes, in a line nearest to the front of the counter, contain specimens of the ore as prepared for smelting, and its various stages of progress until manufactured into lead and the silver separated; these finished products being contained in division No. 5. of this collection.

Case No. 1.—Lead ore, as first separated from the vein in which it is found, and which in this state is called "bouse" in the north of England lead mines, and the places in which it is deposited at the surface are called bouse teams. The depositing of the ore in these places is greatly facilitated at Allenheads by the use of tipping-frames of a new construction, by Mr. W. G. Armstrong, of the Elswick Engine Works, near Newcastle-on-Tyne. This example is from a "flats" vein in Allenheads mines in the great limestone, which rock forms the curiously laminated matrix with which the ore is intermixed. The ore and rock thus intermixed require to be separated as is exhibited by the following examples. By a flat vein, or "flats," is meant a horizontal extension of mineral substances to a considerable distance from the ordinary vertical or steeply-inclined veins, which extend in the manner of fissures through the various beds of rock forming the district. The regular lamination of the ore is worthy of attention, as leading to speculations on the origin of mineral veins; a subject of great practical importance. The example here shown is taken from a part of the "flat workings" at a distance of about 20 feet from the principal or nearly vertical part of the vein.

Case No. 2.—Bouse, or lead ore, as extracted from the vein, and showing an example of the curiously polished surface, which is a frequent characteristic of veins, and which would appear at first sight to have been very carefully polished by artificial means, many of the surfaces being sufficiently clear to reflect the images of objects in a tolerably definite form. The local name of such bright and polished surfaces is "*slickensides*;" and the suggestion mentioned in the notice of the last specimen as to the value of scientific inquiry applies with still greater force to the class of phenomena of which this is one of the most curious indications.

Case No. 3. contains a portion of the ordinary bouse or ore as newly worked from the vein, and much intermixed with the materials contained in Cases 1. and 2., as well as with other earthy and sparry contents of veins. The produce of mineral veins varies from pure galena, of which some species are shown, to masses of rock in spar, in which the ore is so thinly disseminated as not to repay the trouble of extraction.

Case No. 4.—The intermixed rocks and ores shown in preceding cases are first subjected to "picking" and then to "washing" on a grate. The first of these operations separates from the general mass all such pieces of galena as are either not mixed with other substances, or which can be readily separated with a hammer on what are called

"knocking stones;" and the second has the effect of clearing away all earthy matter. These specimens, picked from the heap and washing-grate, are ready for smelting after being reduced with a hammer to the size of the ore contained in Case No. 9.

Case No. 5 contains ordinary bouse or lead ore taken from the *trunking-box* after passing through the *washing-grate*, being, in fact, a process of *washing and sizing* with a view to the further operations exhibited in the following cases.

Case No. 6 contains specimens of ordinary bouse, which, from the size of the pieces and intermixture of rock and ore, require to be passed through the rollers of the crushing-mill.

Case No. 7.—Specimens of the same bouse or ore after having passed through the rollers of the crushing-mill.

Case No. 8.—So far the processes have consisted simply of extraction of the ore from its place in the mine,—of the pure samples of ore being picked out and washed and sized ready for being smelted at once without further operations,—of the remainder of poorer samples being washed and separated by an iron grate or sieve into two sizes, the larger having to be ground between rollers to reduce it to the same size as the smaller, which had passed the grate; and when reduced to this stage, the whole is ready for an operation called "*hotching*," which consists in placing the ore in a tub with water. The bottom of this tub is a sieve,—and the whole is subjected to a rapid vibratory vertical movement or shaking, by which a separation of the ore takes place. The water so far lessens the weight as greatly to facilitate the downward movement of the ore, which of course is much heavier than the spar and other materials connected with it. The vibratory movement is sometimes given by manual labor; a long arm moving with a spring is jerked up and down by a strong lad jumping on a raised stand so as to produce the required motion. The same results may be obtained by machinery; and a model of a hotching apparatus accompanies these specimens. It represents the mode in which the hotching tubs are worked in some of Mr. Beaumont's mines in West Allendale; and both the mode of applying the machinery, and the manufacture of the model representing it, are due to the ingenuity of Mr. Joseph Hetherington, one of the engineers or wrights employed at these mines.

The ore is prepared as has already been described; and after being shaken in the "*hotching tub*," the upper part is entirely waste or refuse, and is called "*cuttings*," of which this case, No. 8, contains a specimen.

Case No. 9 contains lead ore as obtained from the bottom of the hotching-tub, and is ready for being smelted.

Case No. 10 contains what is called "*undressed smeddum*," being what has passed through the sieve of the hotching-tub into the box or case of water in which the hotching-tub vibrates.

Case No. 11 is the "*smeddum*," after being dressed or cleared from all foreign substances in what is locally called a "*buddle*," and the ore in being so washed is said to be "*buddled*."

Case No. 12. In all operations where a stream of running water is employed to wash lead ore, it is obvious that many of the smaller particles will be carried away with the stream. These particles are allowed to settle by their specific gravity in what are called slime pits, being merely reservoirs in which the water passes over a long space with a very tranquil movement. In the Case No. 12 is an example of the slime or deposit in these slime pits undressed.

Case No. 13 contains a specimen of what is called slime ore, having been extracted or separated from the slime shown in Case No. 12. The separation is effected by manual labor in what are called "*nicking-trunks*," and is made ready for a final washing or separation in the "*dolly-tub*."

* Case No. 14 contains slime obtained, not by manual labor, but by means of a patented invention of Mr. Bruton's, by which the slime, being first freely mixed with water, is allowed on a revolving canvas cloth, inclined at a moderate angle, and upon which also drops of water are constantly falling so as to keep the surface well wetted. Heavier particles, being thus free to move, are carried up the slightly inclined surface of the canvas, and pass round a roller to a cistern below, in which they are deposited while the lighter particles of earthy matter and spar are at once carried down the canvas by the stream of water. The ore thus obtained requires finally to be washed in the dolly-tub, after which it is fit for being smelted.

Case No. 15 contains slime ore as taken from the dolly-tub, which is the last operation connected with the washing and dressing of lead ores as usually practiced in the lead mines belonging to Mr. Beaumont, and in the lead mines generally of this part of the kingdom.

The German buddle is also occasionally used in dressing slime ores. A considerable improvement was made in this apparatus about thirty years ago by Mr. Robert Stagg, of Middleton-in-Teesdale.

Case No. 16 exhibits a specimen of "selected" or superior lead ore in the form in which it is sent to and deposited at the smelt mill ready to be smelted.

Case No. 17 contains an example of the ordinary or common lead ore as prepared and ready for smelting.

Cases Nos. 18 and 19 contain the same ores (selected and common), after having undergone the operation of being "roasted," or exposed to suitable temperature in a reverberatory furnace, the object being to free it from the sulphur contained in the galena, pure specimens of which consist of lead 86.6 and sulphur 13.3.

By this process the ore is rendered more easily reducible.

Case No. 20. Gray slags formed in the process of ore hearth smelting, and from which the lead is afterwards obtained at the slag hearth.

Case No. 21. Black slags being the residuum obtained from the slag hearth, and which assume the granulated form from being made to flow, when in a melted state, into water.

Cases Nos. 22 and 23 contain examples of the crystals of selected and common lead as formed in the process of separating or desilvering the ore: patented by Mr. H. L. Pattinson, and first brought into operation at Mr. Beaumont's smelt mills.

Cases Nos. 24, 25, and 26, contain specimens of the fume or deposit in the long flues connected with the smelt mills; that in No. 24 being the ordinary fume collected in the flue: No. 25 the same, after being roasted for the ore hearth, and No. 26 the same roasted for the slag hearth. The flues or chimneys are built of stone, 8 feet by 6 feet inside, and upwards of 8½ miles long.

Cases Nos. 27, 28, and 29. Litharge in the ordinary round state, and two varieties of linseed litharge which have been passed through a sieve.

Case No. 30. Skimmings from the surface of melted lead, showing iridescent hues, which are frequently of great intensity and beauty.

A brief statement of the quantity of coals consumed per month in a few of the principal mines will show the extent to which steam power is now employed.

Mines were worked at an early period in the Isle of Man; but the neighborhood of Laxey first attracted attention at the commencement of the present century. In 1811 only three hands were employed; in 1848 there were at least 800 in the mine. The mine is situated about a mile and a half from the sea, up the Laxey Valley, where an adit is driven 400 fathoms into the heart of the mountain. From this adit the shaft has been sunk about 180 fathoms. The returns of lead ore for the last five years have been as follows:—

Years.				Lead Ore.		Lead.	
				Tons.		Tons.	
1845	-	-	-	327		155	
1846	-	-	-	220		104	
1847	-	-	-	375		247	
1848	-	-	-	695		461	
1849	-	-	-	815		546	

In addition to this, about 200 tons of the sulphuret of zinc are annually raised.

The Cardiganshire mines were worked at a very early period, probably by the Romans. Henry VII. encouraged mining by several grants, involving privileges to those who would work these mines. In the reign of Queen Elizabeth there was a grant made of all these mines to Thomas Thurland and Daniel Houghsetter, Germans, who worked them for some time. They eventually passed into the hands of Sir Hugh Middleton, who realized a large profit by working them.

The present value of the Cardiganshire mines will be seen by the following list of their produce:—

Treatment of the Ores of Lead.

The mechanical operations performed upon the lead ores in Great Britain, to bring them to the degree of purity necessary for their metallurgic treatment, may be divided into three classes, whose objects are,—

1. *The sorting and cleansing of the ores;*
2. *The grinding;*
3. *The washing, properly so called;*

The apparatus subservient to the first objects are sieves, running budles, and gratings. The large sieves employed in Derbyshire for sorting the ore at the mouth of the mine into coarse and fine pieces, is a wire gauze of iron; its meshes are square, and an inch long in each side. There is a lighter sieve of wire gauze, similar to the preceding, for washing the mud from the ore, by agitating the fragments in a tub filled with water.

But in Derbyshire, instead of using this sieve, the pieces of ore are sometimes merely stirred about with a shovel, in a trough filled with water. This is called a *standing buddle*; a most defective plan.

The *running buddle* serves at once to sort and cleanse the ore. It consists of a plane surface made of slabs or planks, very slightly inclined forwards, and provided behind and on the sides with upright ledges, the back one having a notch to admit a stream of water. The ore is merely stirred about with a shovel, and exposed on the slope to the stream. For this apparatus, formerly the only one used at the mines of Alston Moor, the following has been substituted, called the *grate*. It is a *grid*, composed of square bars of iron, an inch thick, by from 24 to 32 inches long, placed horizontally, and parallelly to each other, an inch apart. There is a wooden canal above the grate, which conducts a stream of water over its middle; and an inclined plane is set beneath it, which leads to a hemispherical basin, about 24 inches in diameter, for collecting the metallic powder washed out of the ore.

The apparatus subservient to grinding the ore are,—

1. The *bucker*, or beater, formed of a cast-iron plate, 3 inches square, with a socket in its upper surface, for receiving a wooden handle. In the neighborhood of Alston-Moor, crushing cylinders have been substituted for the beating buckers; but even now, in Derbyshire, buckers are generally employed for breaking the pieces of mixed ore, called *knock-stone-stuff*.

At the mines of this county, the *knocker's workshop*, or *striking floor*, is provided either with a strong stool, or a wall 3 feet high, beyond which there is a flat area 4 feet broad, and a little raised behind. On this area, bounded, except in front, by small walls, the ore to be bruised is placed. On the stool, or wall, a very hard stone slab, or cast-iron plate is laid, 7 feet long, 7 inches broad, and $1\frac{1}{2}$ inches thick, called a *knock-stone*. The workmen seated before it, break the pieces of mixed ore, called *browse* in Derbyshire, with the buckers.

Crushing machines are in general use at Alston Moor, to break the mingled ores, which they perform with great economy of time and labor. They have been employed there for nearly forty years.

This machine is composed of one pair of fluted cylinders, *x x*, fig. 853, and of two pairs of smooth cylinders *z z*, *z' z'*, which serve altogether for crushing the ore. The two cylinders of each of the three pairs turn simultaneously in an inverse direction, by means of two toothed wheels, as at *m*, fig. 854, upon the shaft of every cylinder, which

work by pairs in one another. The motion is given by a single water-wheel, of which the circle *a a a* represents the outer circumference. One of the fluted cylinders is placed in the prolongation of the shaft of this wheel, which carries besides a cast-iron toothed wheel geared with the toothed wheels *e e*, fixed upon the ends of two of the smooth cylinders. Above the fluted cylinders there is a hopper, which discharges down between them, by means of a particular mechanism, the ore brought forward by the wagons *A*. These wagons advance upon a railway, stop above the hopper, and empty their contents into it through a trap-hole, which opens outwardly in the middle

of their bottom. Below the hopper there is a small bucket called a shoe, into which the ore is shaken down, and which throws it without ceasing upon the cylinders, in consequence of the constant jolts given it by a crank-rod *i* (fig. 854) attached to it, and moved by the teeth of the wheel *m*. The shoe is so regulated, that too much ore can never fall upon the cylinders, and obstruct their movement. A small stream of water is likewise led into the shoe, which spreads over the cylinders, and prevents them from growing hot. The ore, after passing between the fluted rollers, falls upon the inclined planes *x, x*, which turn it over to one or other of the pairs of smooth rolls.

These are the essential parts of this machine; they are made of iron, and the smooth ones are case-hardened, or *chilled*, by being cast in iron moulds. The gudgeons of both kinds move in brass bushes fixed upon iron supports *k*, made fast by bolts to the strong wood-work basis of the whole machine. Each of the horizontal bars has an oblong slot, at one of whose ends is solidly fixed one of the plummer-blocks or bearers of one of the cylinders *f*, and in the rest of the slot the plummer-block of the other cylinder *g* slides; a construction which permits the two cylinders to come into contact, or to recede to such a distance from each other, as circumstances may require. The moveable cylinder is approximated to the fixed one by means of the iron levers *x x*, which carry at their ends the weights *r*, and rest upon wedges *m*, which may be slid upon the inclined plane *n*. These wedges then press the iron bar *o*, and make it approach the moveable cylinder by advancing the plummer block which supports its axis. When matters are so arranged, should a very large or hard piece present itself to one of the pairs of cylinders, one of the rollers would move away, and let the piece pass without doing injury to the mechanism.

Besides the three pairs of cylinders which constitute essentially each crushing machine, there is sometimes a fourth, which serves to crush the ore when not in large fragments, for example, the *chats* and *cuttings* (the moderately rich and poorer pieces), produced by the first sifting with the brake sieve, to be presently described. The cylinders composing that accessory piece, which, on account of their ordinary use, are called *chats-rollers*, are smooth, and similar to the rollers *z z*, and *z' z'*. The one of them is usually placed upon the prolongation of the shaft of the water-wheel, of the side opposite to the principal machine; and the other, which is placed alongside, receives its motion from the first, by means of toothed wheel-work.

The *stamp mill* is employed in concurrence with the crushing cylinders. It serves particularly to pulverize those ores whose gangue is too hard to yield readily to the rollers, and also those which being already pulverized to a certain degree, require to be ground still more finely. The stamps employed in the neighborhood of Alston Moor are moved by water wheels. They are similar to those described under *TIN*.

Proper sifting or jigging apparatus.—The hand sieve made of iron wire meshes, of various sizes, is shaken with the two hands in a tub of water, the *ore vat*, being held sometimes horizontally, and at others in an inclined position. This sieve is now in general use only for the *cuttings* that have passed through the grating, and which though not poor enough to require finer grinding, are too poor for the brake sieve. When the workman has collected a sufficient quantity of these smaller pieces, he puts them in his round hand sieve, shakes it in the ore vat with much rapidity and a dexterous toss, till he has separated the very poor portions called *cuttings*, from the mingled parts called *chats*, as well as from the pure ore. He then removes the first two qualities, with a sheet-iron scraper called a *limp*, and he finds beneath them a certain portion of ore which he reckons to be pure.

The *brake sieve* is rectangular, as well as the cistern in which it is agitated. The meshes are made of strong iron wire, three eighths of an inch square. This sieve is suspended at the extremity of a forked lever, or brake, turning upon an axis by means of two upright arms about 5 feet long, which are pierced with holes for connecting them with bolts or pins, both to the sieve-frame and to the ends of the two branches of the lever. These two arms are made of wrought iron, but the lever is made of wood; as it receives the jolt. A child placed near its end, by the action of leaping, jerks it smartly up and down, so as to shake effectually the sieve suspended at the other extremity. Each jolt not only makes the fine parts pass through the meshes, but changes the relative position of those which remain on the wires, bringing the purer and heavier pieces eventually to the bottom. The mingled fragments of galena, and the stony substances called *chats* lie above them; while the poor and light pieces called *cuttings*, are at top. These are first scraped off by the *limp*, next the mixed lumps, or *chats*, and lastly the pure ore, which is carried to the *bing heap*. The *cuttings* are handed to a particular class of workmen, who by a new sifting, divide them into mere stones, or second *cuttings*, and into mixed ore analogous to *chats*.

The poor ore, called *chats*, is carried to a crushing machine, where it is bruised between two cylinders appropriated to this purpose under the name of *chats rollers*; after which it is sifted afresh. During the sifting many parcels of small ore and stony sub-

stances pass through the sieve, and accumulate at the bottom of the cistern. When it is two thirds filled, water is run slowly over it, and the sediment called *smitham* is taken out, and piled up in heaps. More being put into the tub, a child lifts up the *smitham*, and lays it on the sieve, which retains still on its meshes the layer of fine ore. The *sifter* now agitates in the water nearly as at first, from time to time removing with the *limp* the lighter matters as they come to the surface; which being fit for washing only in boxes, are called *buddler's offal*, and are thrown into the *buddle hole*.

Mr. Petherick, the manager of Lanesco and the Fovey Consol mines, has contrived an ingenious jiggging machine, in which a series of 8 sieves are fixed in a stationary circular frame, connected with a plunger or piston working in a hollow cylinder, whereby a body of water is alternately forced up through the crushed ore in the sieves, and then left to descend. In this way of operating, the indiscriminate or premature passage of the finer pulverulent matter through the meshes is avoided, because a regulated stream of water is made to traverse the particles up and down. This mode has proved profitable in washing the copper ores of the above mentioned copper mines.

Proper washing apparatus.—For washing the ore after sifting it, the running buddle already described is employed, along with several chests or *buddles* of other kinds.

1. The *trunk buddle* is a species of German chest (see METALLURGY and TIN) composed of two parts; of a cistern or box into which a stream of water flows, and of a large tank with a smooth level bottom. The ore to be *trunked* being placed in the box, the workman furnished with a shovel bent up at its sides, agitates it, and removes from time to time the coarser portions; while the smaller are swept off by the water and deposited upon the level area.

2. The *stirring buddle*, or chest for freeing the *schlamms* or slimy stuff from clay, is analogous to the German chests, and consists of two parts; namely, 1. a trough which receives a stream of water through a plug hole, which is tempered at pleasure, to admit a greater or less current; 2. a settling tank with a horizontal bottom. The metallic *slime* being first floated in the water of the trough, then flows out and is deposited in the tank; the purest parts falling first near the beginning of the run.

3. The *nickling buddle* is analogous to the tables called *dormantes* or *jumelles* by the French miners. See METALLURGY. They have at their upper end a cross canal or spout, equal in length to the breadth of the table, with a plug hole in its middle for admitting the water. Alongside of this channel there is a slightly inclined plank, called *nickling board*, corresponding to the head of the *twin table*, and there is a nearly level plane below. The operation consists in spreading a thin layer of the *slime* upon the *nickling board*, and in running over its surface a slender sheet of water, which in its progress is subdivided into rills, which gradually carry off the muddy matters, and strew them over the lower flat surface of the tank, in the order of their density.

855

4. The *dolly tub* or rinsing bucket, fig. 855, has an upright shaft which bears the vane or *dolly A*, turned by the winch handle. This apparatus serves to bring into a state of suspension in water, the fine ore, already nearly pure; the separation of the metallic particles from the earthy ones by repose, being promoted by the sides of the tub being struck frequently during the subsidence.

5. *Slime pits.*—In the several operations of cleansing ores from mud, in grinding, and washing, where a stream of water is used, it is impossible to prevent some of the finely attenuated portions of the galena called *sludge*, floating in the water, from being carried off with it. *Slime pits* or *labyrinths*, called *buddle holes* in Derbyshire, are employed to collect that matter, by receiving the water to settle, at a little distance from the place of agitation.

These basins or reservoirs are about 20 feet in diameter, and from 24 to 40 inches deep. Here the suspended ore is deposited, and nothing but clear water is allowed to escape.

The workmen employed in the mechanical preparation of the ores, are paid, in Cumberland, by the piece, and not by day's wages. A certain quantity of crude ore is delivered to them, and their work is valued by the *bing*, a measure containing 14 cwt., of ore ready for smelting. The price varies according to the richness of the ore. Certain qualities are washed at the rate of two and sixpence, or three shillings the *bing*; while others are worth at least ten shillings. The richness of the ore varies from 2 to 20 *blings* of galena per *shift* of ore; the *shift* corresponding to 8 wagon loads.

1. The cleansing and sorting of the ores are well performed in Cumberland. These operations seem however to be inferior to the cleansing on the *grid steps*, *grilles à gradin*, of Saxony (See METALLURGY), an apparatus which in cleaning the ores, has the advantage of grouping them in lots of different qualities and dimensions.

2. The breaking or bruising by means of the *crushing machine*, is much more expeditious than the Derbyshire process by *buckers*; for the machine introduces not only great economy into the breaking operation, but it likewise diminishes considerably the loss of *galena*; for stamped ores may be often subjected to the action of the cylinders without

waste, while a portion of them would have been lost with the water that runs from the stamp mill. The use of these rollers may therefore be considered as one of the happiest innovations hitherto made in the mechanical preparation of ores.

3. The *brake sieves* appear to be preferable to the hand ones.

4. The system of washing used in Cumberland differs essentially from that of Brittany. The slime pits are constructed with much less care than in France and Germany. They never present, as in these countries, those long windings backwards and forwards, whence they have been called labyrinths; probably because the last deposites, which are washed with profit in France and Germany, could not be so in Cumberland. There is reason to believe, however, that the introduction of *brake tables* (*tables à secousses*, see METALLURGY) would enable deposites to be saved, which at present run to waste in England.

5. From what we have now said about the system of washing, and the basins of deposit or settling cisterns, it may be inferred that the operation followed in Cumberland is more expeditious than that used in Brittany, but it furnishes less pure ores, and occasions more considerable waste; a fact sufficiently obvious, since the refuse stuff at Poulläouen is often resumed, and profitably subjected to a new preparation. We cannot however venture to blame this method, because in England, fuel being cheap, and labor dear, there may possibly be more advantage in smelting an ore somewhat impure, and in losing a little galena, than in multiplying the number of washing processes.

6. Lastly, the *dolly tub* ought to be adopted in all the establishments where the galena is mixed with much blende (sulphuret of zinc); for *schlich* (metallic slime) which appears very clean to the eye, gives off a considerable quantity of blende by means of the *dolly tub*. While the vane is rapidly whirled, the sludge is gradually let down into the revolving water, till the quantity is sufficiently great. Whenever the ore is thoroughly disseminated in the liquid, the dolly is withdrawn. The workmen then strike on the sides of the tub for a considerable time, with mallets or wooden billets, to make the slime fall fast to the bottom. The lighter portions, consisting almost entirely of refuse matter, fall only after the knocking has ceased: the water is now run away; then the very poor slime upon the top of the deposit is skimmed off, while the pure ore found at the bottom of the tub is lifted out, and laid on the *bingstead*. In this way the blende, which always accompanies galena in a greater or smaller quantity, is well separated.

Smelting of lead ores.—The lead ores of Derbyshire and the north of England were anciently smelted in very rude furnaces, or *boles*, urged by the natural force of the wind, and were therefore placed on the summits or western slopes of the highest hills. More recently these furnaces were replaced by blast hearths, resembling smiths' forges, but larger, and were blown by strong bellows, moved by men or water-wheels. The principal operation of smelting is at present always executed in Derbyshire in *reverberatory furnaces*, and at *Alston Moor* in furnaces similar to those known in France by the name of Scotch furnaces. Before entering into the detail of the founding processes, we shall give a description of the furnaces essential for both the smelting and accessory operations.

1. The reverberatory furnace called *cupola*, now exclusively used in Derbyshire for the smelting of lead ores, was imported thither from Wales, about the year 1747, by a company of Quakers. The first establishment in this country was built at Kalstedge, in the district of Ashover.

In the works where the construction of these furnaces is most improved, they are interiorly 8 feet long by 6 wide in the middle, and two feet high at the centre. The fire, placed at one of the extremities, is separated from the body of the furnace by a body of masonry, called the *fire-bridge*, which is two feet thick, leaving only from 14 to 18 inches between its upper surface and the vault. From this, the highest point, the vault gradually sinks towards the further end, where it stands only 6 inches above the sole. At this extremity of the furnace, there are two openings separated by a triangular prism of *fire-stone*, which lead to a flue, a foot and a half wide, and 10 feet long, which is recurved towards the top, and runs into an upright chimney 55 feet high. The above flue is covered with stone slabs, carefully jointed with fire-clay, which may be removed when the deposit formed under them (which is apt to melt) requires to be cleaned out. One of the sides of the furnace is called the laborers' side. It has a door for throwing coal upon the fire-grate, besides three small apertures each about 6 inches square. These are closed with moveable plates of cast iron, which are taken off when the working requires a freer circulation of air, or for the stirring up of the materials upon the hearth. On the opposite side, called the working side, there are five apertures; namely, three equal and opposite to those just described, shutting in like manner with cast iron plates, and beneath them two other openings, one of which is for running out the lead, and another for the scorie. The ash pit is also on this side, covered with a little water, and so disposed as that the grate-bars may be easily cleared from the cinder slag.

The hearth of the furnace is composed of the reverberatory furnace slags, to which a

proper shape has been given by beating them with a strong iron rake, before their entire solidification. On the laborers' side, this hearth rises nearly to the surface of the three openings, and falls towards the working side, so as to be 18 inches below the middle aperture. In this point, the lowest of the furnace, there is a tap-hole, through which the lead is run off into a large iron boiler (lea-pan), placed in a recess left outside in the masonry. From that lowest point, the sole gradually rises in all directions, forming thus an inside basin, into which the lead runs down as it is smelted. At the usual level of the metal bath, there is on the working side, at the end furthest from the fire, an aperture for letting off the slag.

In the middle of the arched roof there is a small aperture, called the *crown-hole*, which is covered up during the working with a thick cast iron plate. Above this aperture a large wooden or iron hopper stands, leading beneath into an iron cylinder, through which the contents of the hopper may fall into the furnace when a trap or valve is opened.

2. *The roasting furnace.*—This was introduced about 30 years ago, in the neighborhood of Alston Moor, for roasting the ore intended to pass through the Scotch furnace, a process which greatly facilitates that operation. Since its first establishment it has successively received considerable improvements.

Figs. 856, 857, 858, represent the cupola furnace at the Marquess of Westminster's lead smelting works, two miles from Holywell. The hearth is hollowed out below the middle door of the furnace; it slopes from the back and ends towards this basin. The distance from the lowest point of this concavity up to the sill of the door, is usually 24 inches, but it is sometimes a little less, according to the quality of the ores to be smelted. This furnace has no hole for running off the slag, above the level of the top hole for the lead *i*, like the smelting furnace of Lea, near Matlock. A single chimney stalk serves for all the establishments; and receives all the flues of the various roasting and reducing furnaces. Fig. 858 gives an idea of the distribution of these flues. *a a a*, &c. are the furnaces, *b*, the flues, 18 inches square; these lead from each furnace to the principal conduit *c*, which is 5 feet deep by 2½ wide; *d* is 6 feet deep by 3 wide; *e* is a round chamber 15 feet in diameter; *f* is a conduit 7 feet high by 5 wide; *g* another, 6 feet high by 3 wide. The chimney at *h* has a diameter at bottom of 30 feet, at top of 12 feet including the thickness of its sides, forming a truncated cone 100 feet high; whose base stands upon a hill a little way from the furnaces, and 62 feet above their level.

a, figs. 856, 857, is the grate; *b*, the door of the fire-place; *c*, the fire-bridge; *d* the

arched roof; *c*, the hearth; *f f f*, &c., the working doors; *g g*, flues running into one conduit, which leads to the subterranean condensing-chamber *e*, and thence to the general chimney; *h*, a hopper-shaped opening in the top of the furnace, for supplying it with materials.

This magnificent structure is not destined solely for the reduction of the ores, but for dissipating all the vapors which might prove noxious to the health of the workpeople and to vegetation.

The ores smelted at Holywell are very refractory galenae, mixed with blende, calamine,

pyrites, carbonate of lime, &c., but without any fluxe of lime. They serve mutually as fluxes to one another. The coal is of inferior quality. The sole of each furnace is formed of slags obtained in the smelting, and they are all of one kind. In constructing it, 7 or 8 tons of these slags are first of all thrown upon the brick area of the hearth; are made to melt by a brisk fire, and in their stiffening state, as they cool, they permit the bottom to be sloped and hollowed into the desired shape. Four workmen, two at each side of the furnace, perform this task.

The ordinary charge of ore for one smelting operation is 20 cwt., and it is introduced through the hopper; see COPPER, fig. 375. An assistant placed at the back doors spreads it equally over the whole hearth with a rake; the furnace being meanwhile heated only with the declining fire of the preceding operation. No regular fire is made during the first two hours, but a gentle heat merely is kept up by throwing one or two shovelfuls of small coal upon the grate from time to time. All the doors are closed, and the register-plate of the chimney is lowered.

The outer basin in front of the furnace is at this time filled with the lead derived from a former process, the metal being covered with slags. A rectangular slit above the top hole is left open, and remains so during the whole time of the operation, unless the lead should rise in the interior basin above the level of that orifice; in which case a little mound must be raised before it.

The two doors in front furthest from the fire being soon opened, the head-smelter throws in through them, upon the sole of the furnace, the slags swimming upon the bath of lead, and a little while afterwards he opens the tap-hole, and runs off the metallic lead reduced from these slags. At the same time his assistant turns over the ore with his paddle, through the back doors. These being again closed, while the above two front doors are open, the smelter throws a shovelful of small coal or coke cinder upon the lead bath, and works the whole together, turning over the ore with the paddle or iron bar. About three quarters of an hour after the commencement of the operation, he throws back upon the sole of the hearth the fresh slags which then float upon the bath of the outer basin, and which are mixed with coaly matter. He next turns over these slags, as well as the ore with the paddle, and shuts all the doors. At this time the smelter runs off the lead into the pig-moulds.

The assistant now turns over the ore once more through the back doors. A little more than an hour after the operation began, a quantity of lead proceeding from the slag last remelted, is run off by the tap; being usually in such quantity as to fill one half of the outer basin. Both the workmen then turn over the ore with the paddles, at the several doors of the furnace. Its interior is at this time of a dull red heat; the roasting being carried on rather by the combustion of the sulphurous ingredients, than by the action of the small quantity of coal in the grate. The smelter, after shutting the front doors, with the exception of that next the fire-bridge, lifts off the fresh slags lying upon the surface of the outside bath, drains them, and throws them back into the furnace.

An hour and a half after the commencement, the lead begins to ooze out in small quantities from the ore; but little should be suffered to flow before two hours have expired. About this time the two workmen open all the doors, and turn over the ore, each at his own side of the furnace. An hour and three quarters after the beginning, there are few vapors in the furnace, its temperature being very moderate. No more lead is then seen to flow upon the sloping hearth. A little coal being thrown into the grate to raise the heat slightly, the workmen turn over the ore, and then close all the doors.

At the end of two hours, the *first fire* or roasting being completed, and the doors shut, the register is to be lifted a little, and coal thrown upon the grate to give the *second fire*, which lasts during 25 minutes. When the doors are now opened, the inside of the furnace is of a pretty vivid red, and the lead flows down from every side towards the inner basin. The smelter with his rake or paddle pushes the slags upon that basin back towards the upper part of the sole, and his assistant spreads them uniformly over the surface through the back doors. The smelter next throws in by his middle door, a few shovelfuls of quicklime upon the lead bath. The assistant meanwhile, for a quarter of an hour, works the ore and the slags together through the three back doors, and then spreads them out, while the smelter pushes the slags from the surface of the inner basin back to the upper parts of the sole. The doors being now left open for a little, while the interior remains in repose, the metallic lead, which had been pushed back with the slags, flows down into the basin. This occasional *cooling* of the furnace is thought to be necessary for the better separation of the products, especially of the slags, from the lead bath.

In a short time the workmen resume their rakes, and turn over the slags along with the ore. Three hours after the commencement, a little more fuel is put into the grate, merely to keep up a moderate heat of the furnace during the paddling. After three

hours and ten minutes, the grate being charged with fuel for the *third fire*, the register is completely opened, the doors are all shut, and the furnace is left in this state for three quarters of an hour. In nearly four hours from the commencement, all the doors being opened, the assistant levels the surfaces with his rake, in order to favor the descent of any drops of lead; and then spreads the slags, which are pushed back towards him by the smelter. The latter now throws in a fresh quantity of lime, with the view not merely of covering the lead bath and preventing its oxydization, but of rendering the slags less fluid.

Ten minutes after the third fire is completed, the smelter puts a new charge of fuel in the grate, and shuts the doors of the furnace to give it the *fourth fire*. In four hours and forty minutes from the commencement, this fire being finished, the doors are opened, the smelter pierces the tap hole to discharge the lead into the outer basin, and throws some quicklime upon the slags in the inner basin. He then pushes the slags thus *dried up* towards the upper part of the hearth, and his assistant rakes them out by the back doors.

The whole operation of a *smelting shift* takes about four hours and a half, or at most five hours, in which four periods may be distinguished.

1. The *first fire* for roasting the ores, requires very moderate firing and lasts two hours.

2. The *second fire*, or the smelting, requires a higher heat, with shut doors; at the end the slags are *dried up* with lime, and the furnace is also allowed to cool a little.

3, 4. The last two periods, or the *third and fourth fires*, are likewise two smeltings or foundings, and differ from the first only in requiring a higher temperature. The heat is greatest in the last. The form and dimensions of the furnace are calculated to cause a uniform distribution of heat over the whole surface of the hearth. Sometimes billets of green wood are plunged into the metallic lead of the outer basin, causing an ebullition which favors the separation of the slags, and consequently the production of a purer lead; but no more metallic metal is obtained.

Ten cwt. of coal are consumed at Holywell in smelting one ton of the lead-ore *schlich* or sludge; but at Grassington, near Skipton in Yorkshire, with a similar furnace worked with a slower heat, the operation taking from seven hours to seven hours and a half, instead of five, only $7\frac{1}{2}$ cwt. of coal are consumed. But here the ores are less refractory, have the benefit of fluor spar as a flux, and are more exhausted of their metal, being smelted upon a less sloping hearth.

Theory of the above operation.—At Holywell, Grassington, and in Cornwall, the result of the first graduated roasting heat, is a mixture of undecomposed sulphuret of lead, with sulphate and oxyde of lead, in proportions which vary with the degree of care bestowed upon the process. After the roasting, the heat is raised to convert the sludge into a pasty mass; in which the oxyde and sulphate react upon the sulphuret, so as to produce a sub-sulphuret, which parts with the metal by liquation. The *cooling of the furnace* facilitates the liquation every time that the sub-sulphuret is formed, and the ore has passed by increase of temperature from the pasty into the liquid state. *Cooling* brings back the sludge to the pasty condition, and is therefore necessary for the due separation of the different bodies. The drying up of the thin slags by lime is intended to liberate the oxyde of lead, and allow it to react upon any sulphuret which may have resisted roasting or decomposition. It is also useful as a *thickener*, in a mechanical point of view. The iron of the tools, which wear away very fast, is also serviceable in reducing the sulphuret of lead. The small coal added along with the lime at Grassington, and also sometimes at Holywell, aids in reducing the oxyde of lead, and in transforming the sulphate into sulphuret.

3. *The smelting furnace or ore hearth.*—This furnace, called by the French *écossais*, is from 22 to 24 inches in height and 1 foot by $1\frac{1}{2}$ in area inside; but its horizontal section, always rectangular, varies much in its dimensions at different levels, as shown in *fig. 859*.

The hearth and the sides are of cast iron; the sole-plate *a n* is also of cast iron, 2½ inches thick, having on its back and two sides an upright ledge, *a c*, 2½ inches thick and 4½ high. In front of the hearth there is another cast iron plate *m n*, called the *work-stone*, surrounded on every side excepting towards the sole of the furnace, by a ledge one inch in thickness and height. The plate slopes from behind forwards, and its posterior ledge, which is about 4½ inches above the surface of the hearth, is separated from it by a void space *g*, which is filled with a mixture of bone ash and galena, both in fine powder, moistened and pressed down together. The melted lead cannot penetrate into this body, but after filling the basin at the bottom of the furnace, flows naturally out by the gutter (nearly an inch deep) through a groove in the *work-stone*; and then passes into a caldron of reception *r*, styled the *melting-pot*, placed below the front edge of the *work-stone*.

The posterior ledge of the sole is surmounted by a piece of cast iron *c n*, called the *back-stone*, 28 inches long, and 6½ high; on which the *tuyère* or blast-pipe is placed. It supports another piece of cast iron *e*, called *pipe-stone*, scooped out at its under part, in the middle of its length, for the passage of the *tuyère*. This piece advances 2 inches into the interior of the furnace, the back wall of which is finally crowned by another piece of cast iron *e n*, called also *back-stone*.

On the ledges of the two sides of the sole, are placed two pieces of cast iron, called *bearers*, each of which is 5 inches in breadth and height, and 26 inches long. They advance an inch or two above the posterior and highest edge of the *work-stone*, and contribute effectually to fix it solidly in its place. These bearers support, through the intervention of several ranges of fire-bricks, a piece of cast iron called a *fore-stone*, which has the same dimensions as the piece called the *back-stone*, on which the base of the blowing-machine rests. This piece is in contact, at each of its extremities, with another mass of cast iron, 6 inches cube, called the *key-stone*, supported on the masonry. Lastly, the void spaces left between the two *key-stones* and the back part of the furnace are filled up with two masses of cast iron exactly like the *key-stones*.

The front of the furnace is open for about 12 inches from the lower part of the front cross-piece called *fore-stone*, up to the superior part of the *work-stone*. It is through this opening that the smelter operates.

The gaseous products of the combustion, on escaping from this ore-hearth, are frequently made to pass through a long flue, sloped very slightly upwards, in which they deposit all the particles of ore that they may have swept along; these flues, whose length is sometimes more than 100 yards, are usually 5 feet high and 3 feet wide in the inside, and always terminate in a chimney stalk. The matters deposited near the commencement of the flue require to be washed; but not the other dusty deposits. The whole may then be carried back to the roasting furnace, to be calcined and re-agglutinated, or introduced without any preparation into the *slag hearth*.

4. Figs. 860, 861 represent a slag-hearth, the *fourneau à manche* (elbow furnace) of the

French, and the *krummofen* (crooked furnace) of the Germans; such as is used at Alston Moor, in Cumberland, for the reduction of the lead-slag. It resembles the Scotch furnace. The shaft is a parallelopiped, whose base is 26 inches by 22 in area inside, and whose height is 3 feet; the sole-plate *a*, of cast iron, slopes slightly down to the basin of reception, or the fore-hearth *b*. Upon both of the long sides of the sole-plate there are cast iron beams, called *bearers*, *c c*, of great strength, which support the side walls built of a coarse grained sandstone, as well as the cast iron plate *d* (*fore-stone*), which forms the front of the shaft. This stands 7 inches off from the sole-plate, leaving an empty space between them. The back side is made of cast iron from the sole-plate to the horizontal *tuyère* in its middle; but above this point it is made of sandstone. The *tuyère* is from 1½ to 2 inches in diameter. In front of the fore-hearth *b*, a cistern *e* is placed, through which water continually flows, so that the slags which spontaneously overflow the fore-hearth may become inflated and shattered, whereby the lead disseminated through them may be readily separated by washing. The lead itself flows from the fore-hearth *b*, through an orifice, into an iron pot *f*, which is kept hot over a fire. The metal obtained from this slag-hearth is much less pure than that extracted directly from the ore.

The whole bottom of the furnace is filled to a height of 17 inches, that is, to within 2 or 3 inches of the tuyère, with the rubbish of coke reduced to coarse powder and beat strongly down. At each *smelting shift*, this bed must be made anew, and the interior of the furnace above the tuyère repaired, with the exception of the front, consisting of cast iron. In advance of the furnace there is a basin of reception, which is also filled with coke rubbish. Farther off is a pit, full of water, replenished by a cold stream, which incessantly runs in through a pipe. The scoriae, in flowing out of the furnace, pass over the coke bed in the basin of reception, and then fall into the water, whose coolness makes them fly into small pieces, after which they are easily washed, so as to separate the lead that may be entangled among them.

These furnaces are urged, in general, by wooden bellows; *fig. 862*. But at the smelting

works of Lea, near Matlock, the blowing-machine consists of two casks, which move upon horizontal axes. Each of these casks is divided into two equal parts by a fixed plane that passes through its axis, and is filled with water to a certain height. The water of one side communicates with that of the other by an opening in the lower part of the division. Each cask possesses a movement of oscillation, produced by a rod attached to a crank of a bucket-wheel. At each demi-oscillation, one of the compartments, being in communication with the external air, is filled; while the other, on the contrary, communicates with the nozzle, and supplies wind to the furnace.

5. *Refining or cupellation furnaces.* See SILVER.

6. *Smelting by the reverberatory furnace* is adopted exclusively in Derbyshire, and in some works at Alston Moor. The charge in the hopper consists commonly of 16 cwt., each weighing 120 lbs. avoirdupois, composed of an intimate mixture of 5, 6, 7, or even 8 kinds of ore, derived from different mines, and prepared in different ways. The proportions of the mixture are determined by experience, and are of great consequence to the success of the work.

The ore is rather in the form of grains than of a fine *schlich*; it is sometimes very pure, and affords 75 per cent.; but usually it is mixed up with a large proportion of carbonate and fluato of lime; and its product varies from 65 to 23 per cent.

After scraping the slaggy matters out of the furnace, a fresh smelting shift is introduced at an interval of a few minutes; and thus, by means of two alternate workmen, who relieve each other every seven or eight hours, the weekly operations continue without interruption. The average product in lead of the reverberatory furnaces in Derbyshire, during several years, has been 66 per cent. of the ore. Very fine ore has, however, afforded 76.

7. *Smelting of the drawn slag, on the slag-mill hearth.*—The black slag of the reverberatory furnace is broken by hammers into small pieces, and mixed in proper proportions with the coal cinders that fall through the grate of the reverberatory fire. The leaden *matts* that float on the surface of the bath, and the dust deposited in the chimney, are added, along with some poor ore containing a gangue of fluor spar and limestone, which had been put aside during the mechanical preparation. With such a mixture, the slag-hearth, already described *figs. 860, 861*, is charged. By the action of heat and coal, the lead is revived, the earthy matters flow into very liquid scoriae, and the whole is made to pass across the body of fire into a basin of reception placed beneath. The scoriae are thickened by throwing quicklime upon them, and they are then raked away. At the end of the operation the lead is cast into pigs or ingots of a peculiar form. This is called slag-lead. It is harder, more sonorous than the lead obtained from the reverberatory furnace, and is preferred for the manufacture of minium, lead shot, and some other purposes.

8. *Treatment of lead ores by the Scotch furnace, or ore-hearth.*—This furnace is generally employed in the counties of Northumberland, Cumberland, and Durham, for the smelting of lead ores, which were formerly carried to them without any preparation,

but now they are exposed to a preliminary calcination. The roasted ore yields in the Scotch furnace a more considerable product than the crude ore, because it forms in the furnace a more porous mass, and at the same time it *works drier*, to use the founder's expression; that is, it allows the stream of air impelled by the bellows to diffuse itself more completely across the matters contained in the furnace.

The charge of the *roasting furnace*, figs. 631, 632, 633, is from 9 to 11 cwt. of ore, put into the furnace without any addition. Three such shifts are usually passed through in eight hours. The fire should be urged in such a manner as to produce constantly a dense smoke, without letting any part of the ore melt and form a slag; an accident which would obstruct the principal end of the process, which is to burn off the sulphur and antimony, and to expel the carbonic acid of the carbonate of lead. The ore must be frequently turned over, by moving it from the bridge to the other end and back again. To prevent the ore from running into masses as it cools, it is made to fall out of the furnace into a pit full of water, placed below one of the lateral doors.

Smelting of the lead ores in the Scotch furnace.—When a *smelting shift* has been finished in the Scotch furnace, a portion of the ore, called *browse*, remains in a semi-reduced state, mixed with coke and cinders. It is found of more advantage to preserve the browse for beginning the following operation, than to take raw or even roasted ore. To set the furnace in action, the interior of it is filled with peats, cut into the form of bricks. The peats towards the posterior part are heaped up without order, but those near the front are piled up with care in the form of a wall. A kindled peat is now placed before the nozzle of the bellows, which are made to blow, and the blast spreads the combustion rapidly through the whole mass. To increase the heat, and to render the fire more steady and durable, a few shovelfuls of coals are thrown over the turf. A certain quantity of the browse is to be next introduced; and then (or sometimes before all the browse is put in) the greater part of the matters contained in the furnace is drawn over on the *work-stone*, by means of a large rake called a *gowlock*; the refuse of the ore called *gray slag*, which a skilful smelter knows by its shining more than the browse, is taken off with a shovel, and thrown to the right hand into a corner outside of the furnace. The browse left on the work-stone is to be now thrown back into the furnace, with the addition of a little coal, if necessary. If the browse be not well cleaned from the slag, which is perceived by the whole mass being in a soft state, and showing a tendency to fuse, quicklime must be added, which by its affinity for the argillaceous, siliceous, and ferruginous substances, dries up the materials, as the smelters say, and gives to the earthy parts the property of concreting into lumps or balls; but if, on the other hand, the silicious, argillaceous, or ferruginous parts contained in the ore be too refractory, lime is also to be added, but in smaller quantity, which, by rendering them more fusible, communicates the property of concreting into balls. These lumps, called *gray slag*, contain from one tenth to one fifteenth of the lead which was present in the ore. They must be smelted afterwards at a higher temperature in the slag hearth, to extract their lead. After the browse has been thrown back into the furnace, as has been said, a few shovelfuls of ore are to be strewed over it; but before doing this, and after removing the scoria, there must be always placed before the tuyère half a peat, a substance which being extremely porous and combustible, not only hinders any thing from entering the nozzle of the bellows, but spreads the blast through all the vacant parts of the furnace. After an interval of from 10 to 15 minutes, according to circumstances, the materials in the furnace are drawn afresh upon the work-stone, and the gray slag is removed by the rake. Another peat being placed before the tuyère, and coal and quicklime being introduced in suitable proportions, the browse is thrown back into the furnace, a fresh portion of ore is charged above it, and left in the furnace for the above-mentioned time.

This mode of working, continued for 14 or 15 hours, forms what is called a *smelting shift*; in which time from 20 to 40 cwt. of lead, and even more, are produced.

By this process the purest part of the lead, as well as the silver, are sweated out, as it were, from the materials with which they are mixed, without anything entering into fusion except these two metals in the state of alloy. It is probable that the moderate temperature employed in the Scotch furnace is the main cause of the purity of the lead which it yields.

3. *Smelting of the scoriae of the Scotch furnace on the slag hearth.*—Before putting fire to the slag hearth already described, figs. 635, 636, its empty space is to be filled with peats, and a lighted one being placed before the tuyère, the bellows are made to play. A layer of coke is to be now thrown upon the burning peats, and as soon as the heat is sufficiently high, a layer of the *gray slag* is to be introduced, or of any other scoriae that are to be reduced. From time to time, as the fit moment arrives, alternate strata of coke and slag are to be added. In this operation, though the slag and the lead are brought to a state of perfect fluidity, the metal gets separated by filtering down through the bed of

peat cinders, which the slag cannot do on account of its viscosity. Whenever that coked bed becomes covered with fluid slag, the workman makes a hole in it, of about an inch diameter, by means of a kneed poker; and runs it off by this orifice, as it cannot sink down into the hard rammed cinders, which fill the basin of reception. The slag flows over it in a glowing stream into the pit filled with water, where it gets granulated and ready for washing.

When lead is obtained from galena without the addition of combustible matter, we have an example, on the great scale, of the mutual decomposition of the oxydes and sulphates formed during the roasting heat, by the still undecomposed galena, especially when this action is facilitated by working up and skilfully mingling the various matters, as happens in the reverberatory and Scotch furnaces. It is therefore the sulphuret of lead itself which serves as the agent of reduction in regard to the oxyde and sulphate, when little or no charcoal has been added. Sometimes, however, towards the end of the operation in the reverberatory hearth, it becomes necessary to throw in some wood or charcoal, because the oxydization having become too complete, there does not remain a sufficient body of sulphuret of lead to effect the decompositions and reductions just mentioned, and therefore it is requisite to regenerate some galena by means of carbonaceous matter, which immediately converts the sulphate of lead into the sulphuret. The sulphur and oxygen are eventually all separated in the form of sulphurous acid. Roasted galena contains sometimes no less than 77 per cent. of sulphate of lead.

At Viconago, in the Valais, the process of smelting lead ore in the reverberatory furnace, with the addition of iron, as practised at Vienne, on the Isère, was introduced; but the difficulty of procuring a sufficient supply of old iron has led to an interesting modification.

On the hearth of the reverberatory furnace, 10 quintals of moderately rich ore are spread; these are heated temperately for some time, and stirred about to promote the sublimation of the sulphur. After three or four hours, when the ore seems to be sufficiently desulphureted, the heat is raised so as to melt the whole materials, and whenever they flux into a metallic glass, a few shovelfuls of bruised charcoal or cinders are thrown in, which soon thicken the liquid, and cause metallic lead to appear. By this means three fourths of the lead contained in the ore are usually extracted; but at length the substance, becoming less and less fluid, yields no more metal. Stamped and washed carbonate of iron (sparry iron ore) is now added, in the proportion of about 10 per cent. of the lead ore primarily introduced.

On stirring and working together this mixture, it assumes the consistence of a stiff paste, which is raked out of the furnace. When this has become cold, it is broken into pieces, and thereafter smelted in a slag-hearth, without the addition of flux. By this operation almost the whole lead present is obtained. 100 quintals of schlich yield 45 of argentiferous lead; and in the production of 100 quintals (cwts.) of marketable lead, 140 cubic feet of beech-wood, and 357½ quintals of charcoal are consumed.

This process is remarkable for the use of iron-ore in smelting galena.

10. *Reduction in the reverberatory furnace of the litharge obtained in the refining of lead.*—The litharge of Alston Moor is seldom sold as such, but is usually converted into lead, in a reverberatory furnace.

In commencing this reduction, a bed of coal about 2 inches thick is first of all laid on the hearth; which is soon kindled by the flame of the fire-place, and in a little while is reduced to red hot cinders. Upon these a certain quantity of a mixture of litharge and small coal is uniformly spread; the heat of the fire-place being meanwhile so managed as to maintain in the furnace a suitable temperature for enabling the combustible to deprive the litharge of its oxygen, and to convert it into lead. The metal is run out by the tap-hole into an iron pot; and being cast into pigs of half a hundred weight, is sold under the name of refined lead at a superior price.

The quantity of small coal mixed with the litharge should be somewhat less than what may be necessary to effect the reduction, because if in the course of the process a deficiency of it is perceived in any part of the furnace, more can always be added; whereas a redundancy of coal necessarily increases the quantity of slag, which, at the end of the shift, must be removed from the furnace before a new operation is begun, whereby lead is lost. In the reverberatory furnace, six fodders of lead may be revived in nine or ten hours; during the first six of which the mixture of litharge and coal is added at short intervals. A fodder is from 21 to 24 cwts.

It deserves to be remarked that the work does not go on so well nor so quick when the coal and litharge are in a pulverulent form; because the reduction in this case takes place only at the surface, the air not being able to penetrate into the body, and to keep up its combustion, and the mutual action of the litharge and carbon in the interior. But, on the other hand, when the litharge is in porous pieces, as large as a hen's egg, the action pervades the whole body, and the sooty fumes of the coal effect the reduction

even in the centre of the fragments of the litharge, penetrating into every fissure and carrying off the oxygen. The heat ought never to be urged so far as to melt the litharge.

The grounds of the cupel, and the slag of the reduction furnace, being a mixture of small coke, coal ash, and oxyde of iron, more or less impregnated with lead, are smelted upon the *slag hearth*, along with coke, and, by way of flux, with a certain quantity of the black scorite obtained from the same furnace, prepared for this purpose, by running it out in thin plates, and breaking it into small pieces. The lead thus obtained is usually very white, very hard, and not susceptible of refinement.

MM. Dufrenoy and Beaumont consider the smelting of lead ore by the reverberatory furnace, as practised in Derbyshire, as probably preferable to that with the slag hearth as carried on in Brittany; a process which seldom gives uniform products, while it occasions a more considerable waste of lead and consumption of fuel.

The mixed process employed in Cumberland of roasting the ore, and afterwards smelting it in a small furnace resembling that called the *Scotch*, apparently yields a little less lead than if both operations were executed in the reverberatory furnace; but according to Mr. Forster (see his *Treatise on a Section of the Strata from Newcastle upon Tyne, &c.*), this slight loss is more than compensated by the smaller consumption of fuel, the increased rapidity of the operation, and especially by the much greater purity of the lead obtained from the Scotch furnace. When it comes to be refined, the loss is only about one twelfth or one thirteenth, whereas the lead revived in the reverberatory furnace loses frequently a ninth. Moreover, the lead furnished by the first method admits of being refined with profit, when it yields only 5 ounces of silver per fodder of 20 quintals, *poids de marc*, while that produced by the reverberatory furnace cannot be cupelled unless it gives 10 ounces per fodder; and as in the English cupellation lead is constantly added anew without skimming, the litharge obtained in the second case can never be brought into the market, whereas the litharge of the leads from the Scotch furnace is of good quality. See the new method of enriching lead for cupellation, under SILVER.

As the *smelting* of galena, the principal ore of lead, is not a little complex, the following tabular view of the different processes may prove acceptable to the metallurgist:—

		Treatment of	Process of	
I. Class. Treated in reverberatory furnaces.	A Desulphuration by roasting.	1. Pure ores.	Pesey, Spain, &c.	
		2. Ores mixed with saline gangues.	England, in general.	
		3. Ores mixed with earthy gangues.	Vicenago, in Italy, and Redruth, in Cornwall.	
		4. Ores mixed with several sulphurets.	Combined with the above.	
		5. Ores with earthy, saline, and sulphurous gangues.		
	B Desulphuration by iron.	6. Ores with mattes, as at Vienne, in Dauphiny.	Vienne, Poulläouen, and Tarnowitz.	
II. Class. Treated in the mill-slag-hearth, the <i>fourneau à manche</i> , or Scotch furnace.	A Founding after roasting in a heap, or in a reverberatory.	7. Ores producing slags of various silicates.	Mattes, with raw lead.	Many places.
			Workable lead, without mattes.	Villefort.
	B Founding with direct desulphuration, by metallic iron.	8. Ores producing compound silicate slags.	Mattes and workable lead.	Several places.
			Workable lead.	Pont Gibaud and Scotch furnace.
		9. Ores producing slags composed of silicates and subsilicates.	Mattes and workable lead.	Baad-Ems Hartz, Tarnowitz.
			Poor mattes and workable lead.	Tarnowitz.

The annual production of lead in Europe may be estimated at about 80,000 tons; of which four sevenths are produced in England, two sevenths in Spain, the remainder in Germany and Russia. France does not produce more than one five-hundredth part of the whole; and only one fiftieth of its consumption.

See LITHARGE, MINIMUM, or *Red Lead*, SOLDER, SUGAR OF ACETATE OF LEAD, TYPE METAL, and WHITE LEAD.

LEAD-SHOT (*Plomb de chasse*, Fr.; *Schrot*, *Flintenschrot*, Germ.). The origin of most of the imperfections in the manufacture of lead-shot is the too rapid cooling of the spherules by their being dropped too hot into the water, whereby their surfaces form a solid crust, while their interior remains fluid, and, in its subsequent concretion, shrinks, so as to produce the irregularities of the shot.

The patent shot towers originally constructed in England obviate this evil by exposing the fused spherules after they pass through the cullender, to a large body of air during their descent into the water tub placed on the ground. The greatest erection of this kind is probably at Villach, in Carinthia, being 240 Vienna, or 249 English feet high.

The quantity of arsenic added to the mass of melted lead, varies according to the quality of this metal; the harder and less ductile the lead is, the more arsenic must be added. About 3 pounds of either white arsenic or orpiment is enough for one thousand parts of soft lead, and about 8 for the coarser kinds. The latter are employed preferably for shot, as they are cheaper and answer sufficiently well. The arsenical alloy is made either by introducing some of this substance at each melting, or by making a quantity of the compound considerably stronger at once, and adding a certain portion of this to each charge of lead. If the particles of the shot appear lens shaped, it is a proof that the proportion of arsenic has been too great; but if they are flattened upon one side, if they are hollowed in their middle, called *cupping* by the workman, or drag with a tail behind them, the proportion of arsenic is too small.

The following is the process prescribed by the patentees, Ackerman and Martin. Melt a ton of soft lead, and sprinkle round its sides, in the iron pot, about two shovelfuls of wood ashes, taking care to leave the centre clear; then put into the middle about 40 pounds of arsenic to form a rich alloy with the lead. Cover the pot with an iron lid, and lute the joints quickly with loam or mortar, to confine the arsenical vapors, keeping up a moderate fire to maintain the mixture fluid for three or four hours; after which skim carefully, and run the alloy into moulds to form ingots or pigs. The composition thus made is to be put in the proportion of one pig or ingot into 1000 pounds of melted ordinary lead. When the whole is well combined, take a perforated skimmer and let a few drops of it fall from some height into a tub of water. If they do not appear globular, some more arsenical alloy must be added.

Lead which contains a good deal of pewter or tin must be rejected, because it tends to produce elongated drops or tails.

From two to three tons are usually melted at once in the large establishments. The surface of the lead gets covered with a crust of oxide of a white spongy nature, sometimes called *cream* by the workmen, which is of use to coat over the bottom of the cullender, because without such a bed the heavy melted lead would run too rapidly through the holes for the granulating process, and would form oblong spheroids. The mounting of this filter, or lining of the cullender, is reckoned to be a nice operation by the workmen, and is regarded usually as a valuable secret.

The cullenders are hollow hemispheres of sheet iron, about 10 inches in diameter, perforated with holes, which should be perfectly round and free from burrs. These must be of a uniform size in each cullender; but of course a series of different cullenders, with sorted holes for every different size of lead shot, must be prepared. The holes have nearly the following diameters for the annexed numbers of shot.

No. 0.	-	-	-	-	-	-	$\frac{1}{50}$	of an inch.
1.	-	-	-	-	-	-	$\frac{1}{58}$	—
2.	-	-	-	-	-	-	$\frac{1}{66}$	—
3.	-	-	-	-	-	-	$\frac{1}{72}$	—
4.	-	-	-	-	-	-	$\frac{1}{80}$	—

From No. 5 to No. 9 the diameter decreases by regular gradations, the latter being only $\frac{1}{860}$ of an inch.

The operation is always carried on with three cullenders at a time; which are supported upon projecting grates of a kind of chafing dish made of sheet iron somewhat like a triangle. This chafing dish should be placed immediately above the fall; while at its bottom there must be a tub half filled with water for receiving the granulated lead. The cullenders are not in contact, but must be parted by burning charcoal, in order to keep the lead constantly at the proper temperature, and to prevent its solidifying in the filter. The temperature of the lead bath should vary with the size of the shot; for the largest, it

should be such that a bit of straw plunged into it will be scarcely browned, but for all it should be nicely regulated. The height from which the particles should be let fall varies likewise with the size of the shot; as the congelation is the more rapid, the smaller they are. With a fall of 33 yards or 100 feet, from No. 4 to No. 9 may be made; but for larger sizes, 150 feet of height will be required.

Every thing being arranged as above described, the workman puts the filter-stuff into the cullender, pressing it well against the sides. He next pours lead into it with an iron ladle, but not in too great quantity at a time, lest it should run through too fast. The shot thereby formed and found in the tub are not all equal.

The centre of the cullender being less hot affords larger shot than the sides, which are constantly surrounded with burning charcoal. Occasionally, also, the three cullenders employed together may have holes of different sizes, in which case the tub may contain shot of very various magnitudes. These are separated from each other by square sieves of different fineness, 10 inches broad and 16 inches long, their bottoms being of sheet iron, pierced with holes of the same diameters as those of the cullenders. These sieves are suspended by means of two bands above boxes for receiving the shot; one sieve being usually set above another in consecutive numbers, for instance, 1 and 2. The shot being put into the upper sieve, No. 0 will remain in it, No. 1 will remain in the lower sieve, and No. 2 will, with all the others, pass through it into the chest below. It is obvious that by substituting sieves of successive fineness, shot of any dimension may be sorted.

In the preceding process the shot has been sorted to size; it must next be sorted to form, so as to separate all the spheroids which are not truly round, or are defective in any respect. For this purpose a board is made use of about 27 inches long and 16 broad, furnished partially with upright ledges; upon this tray a handful or two of the shot to be sorted being laid, it is inclined very slightly, and gently shaken in the horizontal direction, when the globular particles run down by one edge, into a chest set to receive them, while those of irregular forms remain on the sides of the tray, and are reserved to be remelted.

After being sorted in this way, the shot requires still to be smoothed and polished bright. This object is effected by putting it into a small octagonal cask, through a door in its side, turning upon a horizontal iron axis, which rests in plummer boxes at its ends, and is made to revolve by any mechanical power. A certain quantity of plumbago or black lead is put in along with the shot.

LEAD acted on by pure water so as to make it poisonous.—Dr. H. Guenau de Mussy was summoned to Claremont in the beginning of October, 1848; and on his arrival was shown into the room of one of the members of the ex-royal family of France, who had been residing there since the preceding March. He found him lying down, with an anxious countenance, the conjunctiva of a yellowish color, and the flesh flabby, evidently proving a loss of substance. He told him he had been suffering for several days from violent colics, which had been relieved after a constipation of two days by abundant alvine evacuations, produced by a purgative draught. This was the third attack of the same nature during the space of five weeks. Some time before, towards the end of July, he had been suffering from colic, with nausea, frequent eructations and irregularity of the bowels.

"I learnt that a brother of my patient had experienced the same symptoms; but no one was astonished at it, as it was supposed he was suffering under a liver complaint contracted on the western coast of Africa.

"A third patient, of forty-eight years of age, who was also subject to constipation, had violent colic a few days before, attended with nausea and even vomiting.

"A few days elapsed, and no bad symptoms disturbed our security. My patients had resumed their usual occupations, and good appetites and pretty fair digestion, but were still very weak; and pale sallow complexions had replaced the icteric color.

"My delusions did not last long. About ten days after, a new access of symptoms began, with a painful sensation of constriction about the epigastric region, anxiety, nausea, and eructations."

After describing the symptoms and the treatment resorted to before the real cause of the disorder was suspected, the doctor mentions the circumstances which led to the discovery, which induced him to administer sulphur in combination with iron internally, and to order sulphurous and soapy baths. He proceeds:—

"The chemical action showed itself almost immediately by the black discoloration of the nails of the feet and hands, and by the appearance of similar spots on different parts of the skin.

"One of the patients came out from the second bath with the abdomen entirely black. The soapy frictions and baths usually washed away the spots from the skin, but not those of the nails. The appearance of this reaction, which is very common with men

working in lead manufactories when using sulphurous baths, is explained by the combination of sulphur with the saturnine molecules adhering to the skin.

"In these cases it was evident that the lead was brought to the surface of the body by means either of subdraminal or follicular exhalations, and perhaps by both.

"The metal is eliminated and transformed into sulphuret of lead by the sulphurous baths, and then taken off by the soapy frictions and baths.

"These were not useless, for without them the lead deposited on the surface might have been carried again by absorption into the economy.

"But the skin was not the only means of giving exit to the poison. I discovered it in the urine by a solution of hydrosulphate of ammonia. Some physicians and chemists look on sulphur as the only efficacious remedy; others, on the contrary, assert that it is without any effect.

"What I can tell you is, that the success was beyond my hopes. After two or three weeks I had the satisfaction of seeing my patients progressing rapidly and surely towards recovery. This happy result induced me to try the same means with another person, older and of a weaker constitution, and consequently for whom I was most uneasy, and the result was as satisfactory.

"One of my patients was accustomed to drink Vichy water at table. This was a very unfortunate predisposing circumstance: it is probable that the salt of Vichy water, i. e. bicarbonate of soda, united to the bed of Claremont water, had much to do with the violence of the attack under which he suffered.

"At the time of my arrival at Claremont, there were thirty-eight inhabitants.

"Thirteen of these had been attacked, eleven men and two women. Four of them had some symptoms two months previously to my arrival, the other cases occurred under my own eyes. Some even after the pipes had been cut off were affected, and on the continent a week after leaving England.

"Six children in the household, aged from three to seven years, have been exempt from it. Only half of the patients have had the gums marked with the slate-colored line and spots of the same color on the mucous membrane of the mouth, and these spots and the bluish line of the gums, were observed on several others who did not experience or exhibit anything else, and those signs of the poison having been taken into the economy have not yet disappeared. The morbid cause has acted in these cases, as it often does, with caprice, and according to individual dispositions which defy every reasoning.

"The malady has shown no respect for condition, and attacked indiscriminately servants, aides-de-camps and princes.

"The spring that furnishes the palace of Claremont with water issues from a sand bed at about two miles distance. It was chosen for its uncommon purity from among a great many others in its vicinity, and the water was thirty years ago conducted to the palace through leaden pipes. In the present day some other metal would perhaps have been selected, for experience has taught us that pure water, and especially distilled water, acts rapidly on lead when it comes in contact with it.

"Thus Tronchin proved that the inhabitants of Amsterdam were indebted to the rain water, kept in leaden cisterns, for the colic they were so much subject to in his time.

"The purity of the Claremont water becomes a most dangerous property, and not only to it but to other springs. Whilst I was combating its pernicious effects, I heard that there had been several similar cases in different parts of England; they are not uncommon in the county of Surrey, and especially in the neighborhood of Claremont. Besides the cases published by Dr. Thompson, I know of several others at Weybridge, Windsor, and in different other places.

"I should inform you that Professor Hoffman has ascertained the quantity of metallic lead contained in the water examined by him. He has found that it amounted to a grain per gallon, an enormous quantity when we consider that the poisoned water was used in all culinary and table purposes; and, previously to the discovery of its deleterious character, even in the preparation of ptisans and lavements."

LEAD SHOT has been manufactured in the United States in low towers, provided with an ascending stream of air, drawn up by a fan worked by water power, whereby a like cooling effect is obtained as by letting the melted lead fall from a high tower.

LEATHER, (*Cuir*, Fr.; *Leder*, Ger.); is the skin of animals, so modified by chemical means as to have become unalterable by the external agents which tend to decompose it in its natural state. The preparation in a rude manner of this valuable substance has been known from the most ancient times, but it was not till the end of the last, and the beginning of the present century, that it began to be manufactured upon right principles, in consequence of the researches of Macbride, Deyeux, Seguin, and Davy. There are several varieties of leather; such as sole leather, boot, or upper leather, shamoy leather, kid or glove leather, &c. Skins may be converted into leather either with or without their hairy coat.

We shall treat first of sole and upper leathers, being the most important, and most

costly and difficult to prepare in a proper manner. These kinds consist of organized fibrous gelatine or skin, combined with the proximate vegetable principle, tannin, and probably also some vegetable extractive. Under the articles GALLS and TANNIN, will be found an account of the properties of this substance, and the means of obtaining it in a state of purity. Calf leather quickly tanned by an infusion of galls, consists of 61 parts of skin, and 39 of vegetable matter in 100 by weight; by solution of catechu, it consists of 80 of skin, and 20 of vegetable matter; by infusion of Leicester willow, of 74.5 skin, and 25.5 vegetable matter; and by infusion of oak bark, of 73.2 skin, and 26.8 vegetable matter. By the slow process of tanning, continued for three months, the increase of weight upon the skin in its conversion into leather, is greatly less; the vegetable constituents being from Leicester willow only 13 per cent. of the leather, and from oak bark 15 per cent. Sole leather, however, generally contains no less than 40 per cent. of vegetable matter. In every astringent bark, the inner white part next to the *alburnum*, contains the largest quantity of tannin, and the middle colored part contains most extractive matter. The outer surface or epidermis seldom furnishes either tannin or extractive matter. Young trees abound most in the white cortical layers, and are hence more productive of tannin under equal weights, than the barks of old trees. In no case is there any reason to believe that the gallic acid of astringent vegetables is absorbed in the process of making leather; hence Seguin's theory of the agency of that substance in disoxygenating skin, falls to the ground. The different qualities of leather made with the same kind of skin, seem to depend very much upon the different quantities of extractive matter it may have absorbed. The leather made with infusion of galls, is generally harder and more liable to crack than the leather obtained from infusions of barks; and it always contains a much larger proportion of tannin, and a smaller proportion of extractive matter.

When calf skin is slowly tanned in weak solutions of the bark, or of catechu, it combines with a good deal of extractive matter, and though the increase of the weight of the skin be comparatively small, yet it has become perfectly insoluble in water, forming a soft, but at the same time a strong leather. The saturated infusions of astringent barks contain much less extractive matter in proportion to their tannin, than the weak infusions; and when skin is quickly tanned in the former, it produces a worse and less durable leather than when slowly tanned in the latter. In quick tanning, a considerable quantity of vegetable extractive matter is thus lost to the manufacturer, which might have been made to enter as a useful constituent into the leather. These observations show that there is sufficient foundation for the opinion of the common workmen, concerning what is technically called *feeding* of leather, in the slow method of tanning; and though the processes of this art have been unnecessarily protracted by defective methods of steeping, and want of progressive infiltration of the astringent liquor through the skins, yet in general they appear to have arrived, in consequence of old experience, at a degree of perfection in the quality of the leather, which cannot be far exceeded by means of any theoretical suggestions which have been advanced.

On the first view it may appear surprising, that in those cases of quick tanning, where extractive matter forms a certain portion of the leather, the increase of weight is less than when the skin is combined with the pure tannin; but the fact is easily accounted for, when we consider that the attraction of skin for tannin must be probably weakened by its union with extractive matter; and whether we suppose that the tannin and extractive matter enter together into combination with the matter of skin, or unite with separate portions of it, still, in either case, the primary attraction of skin for tan must be to a certain extent diminished.

In examining astringent vegetables in relation to their power of making leather, it is necessary to take into account not only the quantity they may contain of the substance precipitable by gelatine, but likewise the quantity and the nature of the extractive matter; and in cases of comparison, it is essential to employ infusions of the same degree of concentration.

Of all astringent substances hitherto examined, catechu is that which contains the largest proportion of tannin; and in supposing, according to the usual estimation, that from four to five pounds of common oak bark are required to produce one pound of leather, it appears, from the various synthetical experiments, that about half a pound of catechu would answer the same purpose. Mr. Purkis found, by the results of different accurate experiments, that 1 pound of catechu was equivalent to 7 or 8 of oak bark. For the common purposes of the tanner, 1 pound of it would be equivalent also to 24 pounds of galls, to 7½ of the Leicester willow, to 11 of the bark of the Spanish chestnut, to 18 of the bark of the common elm, to 21 of the bark of the common willow, and to 3 pounds of sumach.

Various menstrua have been proposed for the purpose of expediting and improving the process of tanning, among others, lime water, and solution of pearl-ash; but as these two substances form compounds with tannin which are not decomposable by gelatine, it

follows that their effects must be prejudicial. There is very little reason to suppose that any bodies will be found which, at the same time that they increase the solubility of tannin in water, will not likewise diminish its attraction for skin.

In this country all tanned leather is distinguished into two kinds, called *hides* and *skins*; the former term being appropriated to that made from the larger animals, as bulls, buffaloes, oxen, and cows, into thick strong sole leather; and the latter to that made from calves, seals, &c., into thinner and more flexible upper leather. Sometimes the hides are brought into the market merely dried, as from Buenos Ayres; or dried and salted, as from Bahia and Pernambuco; but the greater part are fresh from recently slaughtered animals. The heaviest ox-hides are preferred for forming *butts* or *backs*, which are manufactured as follows:—

The washing process must be more or less elaborate, according to the state of the skins. Those that are salted and dry require to be steeped, beaten, and rubbed several times alternately, to bring them to the fresh condition.

After removing the horns, the softened or recent hides are laid in a heap for two or three days, after which they are suspended on poles in a close room called a smoke-house, heated somewhat above the common temperature by a smouldering fire. In these circumstances, a slight putrefaction supervenes, which loosens the epidermis, and renders the hair easily detachable by the *fleshing knife*; a large two handled implement, with a blunt edge, and bent to suit the curvature of the rounded beam of the wooden horse upon which the hide is scraped. See CURRYING.

The next step is immersion in a pit containing water impregnated with about a 1000th part of sulphuric acid. This process is called *raising*, because it distends the pores, and makes the fibres swell, so as to render the skins more susceptible of the action of the tanning infusions. Forty-eight hours in general suffice for this operation, but more time may be safely taken.

When the hides are found to be sufficiently raised, they are transferred to a pit, in which they are stratified with oak bark, ground by a proper mill into a coarse powder. The pit is then filled up with an infusion of oak bark called *ooze*, and the hides are allowed to remain in it for about a month or six weeks. By this time the tannin and extractive matter of the bark having combined intimately with the animal fibre, the pit is exhausted of its virtue, and must be renewed, by taking out the spent bark, and subjecting the skins to a fresh dose of oak bark and *ooze*. The hides which were placed near the top of the first pit, must be placed near the bottom of the next. In this mixture they remain, upon the old practice, about three months. The last process being repeated twice or thrice, perfectly tanned leather is the result. The hides are now removed from the pit, and hung up in a shed. In the progress of drying, which should be slow, they are compressed with a steel tool, and beaten smooth, to render them more firm and dense.

Some manufacturers place on the bottom of the pit 5 or 6 inches of spent bark, over it 2 inches of fresh bark, then a skin; and so, alternately, a layer of new bark and a skin, till the pit is nearly full, reserving a small space at top for a thicker layer of bark, over which weighted boards are laid, to condense the whole down into the tanning infusion.

The operation of tanning sole leather in the above way, lasts a year or a year and a half, according to the quality wanted, and the nature of the hides.

A perfect leather is recognised by its section, which should have a glistening marbled appearance, without any white streaks in the middle.

Crop hides are manufactured by immersion, during three or four days, in pits containing milk of lime; in which they are occasionally moved up and down in order to expose them equally to the action of this menstruum. They are then removed, and cleared from hair and impurities, by using the fleshing knife upon the horse; after which they must be completely freed from the lime by a thorough washing. They are next plunged in pits containing a weak *ooze* or infusion of oak bark, from which they are successively transferred into other pits with stronger *ooze*; all the while being daily *handled*, that is, moved up and down in the infusion. This practice is continued for about a month or six weeks. They are now ready to be subjected to a mixture of ground oak bark and stronger *ooze* in other pits, to a series of which they are progressively subjected during two or three months.

The hides are next put into large vats, called *layers*, in which they are smoothly stratified with more oak bark, and a stronger infusion of it. After six weeks they are taken out of these vats, and subjected to a new charge of the same materials for two months. This simple process is repeated twice or thrice, at the option of the manufacturer, till the hides are thoroughly tanned. They are then slowly dried, and condensed in the manner above described. These *crop hides* form the principal part of the sole leather used for home consumption in England.

The process of tanning *skins* (as of calves, seals, &c.) is in some respects peculiar. They are left in the lime pits for about twelve days, when they are stripped of their

nair, washed in water, then immersed in a lixivium of pigeons' dung, called a *grainer*, of an alkaline nature. Here they remain from eight to ten days, according to the state of the atmosphere, during which time they are frequently handled, and scraped on both sides upon a convex wooden beam. This scraping or *working*, as it is termed, joined to the action of the *grainer*, serves to separate the lime, oil, and glutinous matter, and to render the skin pliant, soft, and ready to imbibe the tanning principle. They are with this view transferred into pits containing a weak solution of bark, in which they undergo nearly the same treatment as described above for *crop* hides; but they are not commonly stratified in the layers. The time occupied in tanning them is usually limited to three months. They are then dried, and disposed of to the currier, who dresses and blackens them for the upper leathers of boots and shoes, for harness, and other purposes. The light and thin sorts of cow and horse hides are often treated like calf skins.

In all the above processes, as the animal fibres on the surface of the skin absorb most readily the tanning principles, and thereby obstruct, in a certain degree, their passage into the interior fibres, especially of thick hides, it becomes an object of importance to contrive some method of overcoming that obstacle, and promoting the penetration of the tan. The first manufacturer who appears to have employed efficacious mechanical means of favoring the chemical action was Francis G. Spilsbury, who in April, 1823, obtained a patent for the following operation:—After the hides are freed from the hairs, &c. in the usual way, they are minutely inspected as to their soundness, and if any holes be found, they are carefully sewed up, so as to be water tight. Three frames of wood are provided of equal dimensions, fitted to each other, with the edges of the frames held together by screw bolts. A skin about to be tanned is now laid upon the frame, and stretched over its edges, then the second frame is to be placed upon it, so that the edges of the two frames may pinch the skin all round and hold it securely; another such skin is then stretched over the upper surface of the second frame, in like manner, and a third frame being set upon this, confines the second skin. The three frames are then pinched tightly together by a series of screw bolts, passing through ears set round their outer edges, which fix the skin in a proper manner for being operated upon by the tanning liquor.

A space has been thus formed between the two skins, into which, when the frames are set upright, the infusion is introduced by means of a pipe from the cistern above, while the air is permitted to escape by a stopcock below. This cock must of course be shut whenever the bag is filled, but the one above is left open to maintain a communication with the liquor cistern, and to allow the hydrostatic pressure to force the liquor through the cutaneous pores by a slow infiltration, and thus to bring the tannin into contact with all the fibres indiscriminately. The action of this pressure is evinced by a constant perspiration on the outer surfaces of the skins.

When the tanning is completed, the upper stopcock is closed, and the under is opened to run off the liquor. The frames are now removed, the bolts are unscrewed, and the pinched edges of the skins pared off; after which they are to be dried and finished in the usual manner.

A modification of this ingenious and effectual process was made the subject of a patent, by William Drake, of Bedminster, tanner, in October, 1831. The hides, after the usual preparatory processes, are immersed in a weak tan liquor, and by frequent handling or turning over, receive an incipient tanning before being submitted to the infiltration plan. Two hides, of nearly the same size and shape as possible, are placed grain to grain, when their corresponding edges are sewed firmly together all round by shoemakers' waxed thread, so as to form a bag sufficiently tight to hold tan liquor. This bag must then be suspended by means of loops sewed to its shoulder end, upon pegs, in such a manner that it may hang within a wooden-barred rack, and be confined laterally into a book form. About an inch of the bag is left unsewed at the upper end, for the purpose of introducing a funnel through which the cold tan liquor is poured into the bag till it be full. After a certain interval which varies with the quality of the hides, the outer surface becomes moist, and drops begin to form at the bottom of the bag. These are received in a proper vessel, and when they accumulate sufficiently may be poured back into the funnel; the bag being thus, as well as by a fresh supply from above, kept constantly distended.

When the hides are observed to feel hard and firm, while every part of them feels equally damp, the air of the tanning apartment having been always well ventilated, is now to be heated by proper means to a temperature gradually increasing from 70° to 150° of Fahrenheit's scale. This heat is to be maintained till the hides become firmer and harder in all parts. When they begin to assume a black appearance in some parts, and when the tan liquor undergoes little diminution, the hides may be considered to be tanned, and the bag may be emptied by cutting a few stitches at its bottom. The outer edges being pared off, the hides are to be finished in the usual way. During

their suspension within the racks, the hides should be shifted a little sideways, to prevent the formation of furrows by the bars, and to facilitate the equable action of the liquor.

By this process the patentee says, that a hide may be tanned as completely in ten days as it could be in ten months by the usual method. I have seen a piece of sole leather thus rapidly tanned, and it seemed to be perfect. How it may wear, compared with that made in the old way, I cannot pretend to determine.

Messrs. Knowlys and Duesbury obtained a patent in August, 1826, for accelerating the impregnation of skins with tannin, by suspending them in a close vessel, from which the air is to be extracted by an air pump, and then the tanning infusion is to be admitted. In this way, it is supposed to penetrate the hide so effectually as to tan it uniformly in a short time.

About 32 years ago, a similar vacuum scheme was employed to impregnate with weavers' paste or starch, the cops of cotton web, for the dandy looms of Messrs. Radcliff and Ross, of Stockport.

Danish leather is made by tanning lamb and kid skins with willow bark, whence it derives an agreeable smell. It is chiefly worked up into gloves.

Of the tawing or dressing of skins for gloves, and white sheep leather.

The operations of this art are: 1. washing the skins; 2. properly treating them with lime; 3. taking off the fleece; 4. treatment in the leather steep.

A shed erected upon the side of a stream, with a cistern of water for washing the skins; wooden horses for cleaning them with the back of the fleshing knife; pincers for removing the fibres of damaged wool; a plunger for depressing the skins in the pits; a lime pit; a pole with a bag tied to the end of it; a two-handed fleshing knife; a rolling pin, from 15 to 18 inches long, thickened in the middle; such are some of the utensils of a tawing establishment. There must be provided also a table for applying the oil to the skins; a fulling mill, worked by a water-wheel or other power; a dressing peg; a press for squeezing out the fatty filth; a stove; planks mounted upon legs, for stretching the skins, &c.

Fresh skins must be worked immediately after being washed, and then dried, otherwise they ferment, and contract either indelible spots, or get tender in certain points, so as to open up and tear under the tools. When received in the dry state they should be steeped in water for two days, and then treated as fresh skins. They are next strongly rubbed on the convex horse-beam with a round-edged knife, in order to make them pliant. The rough parts are removed by the fleshing knife. One workman can in this way prepare 200 skins in a day.

The flesh side of each being rubbed with a cold cream of lime, the skins are piled together with the woolly side of each pair outermost, and the flesh sides in contact. They are left in this state for a few days, till it is found that the wool may be easily removed by plucking.

They are next washed in running water, to separate the greater part of the lime, stripped of the wool by small spring tweezers, and then fleeced smooth by means of the rolling-pin, or sometimes by rubbing with a whetstone. Unless they be fleeced soon after the treatment with lime, they do not well admit of this operation subsequently, as they are apt to get hard.

They are now steeped in the milk of lime-pit, in order to swell, soften, and cleanse them; afterwards in a weak pit of old lime-water, from which they are taken out and drained. This steeping and draining upon inclined tables, are repeated frequently during the space of 3 weeks. Only the skins of young animals, or those of inferior value, are tawed. Sometimes the wool is left on, as for housings, &c.

The skins, after having been well softened in the steeps, are rubbed on the outside with a whetstone set in a wooden case with two handles, in order to smooth them completely by removing any remaining filaments of wool. Lamb skins are rubbed with the pin in the direction of their breadth, to give them suppleness; but sheep skins are filled with water alone. They are now ready for the branning, which is done by mixing 40 lbs. of bran with 20 gallons of water, and keeping them in this fermentable mixture for three weeks—with the addition, if possible, of some old bran water. Here they must be frequently turned over, and carefully watched, as it is a delicate operation. In the course of two days in summer, and eight in winter, the skins are said to be raised, when they sink in the water. On coming out of the bran, they are ready for the white stuff; which is a bath composed of alum and sea-salt. Twelve, fourteen, and sometimes eighteen pounds of alum for 100 skins, form the basis of the bath; to which two and a half pounds of salt are added in winter, and three in summer. These ingredients are introduced into a copper with twelve gallons of water. The salt aids in the whitening action. When the solution is about to boil, three gallons of it are

passed through the cullender into a basin; in this 26 skins are worked one after another, and, after draining, they are put together into the bath, and left in it for ten minutes to imbibe the salts. They are now ready to receive the paste. For 100 skins, from 13 to 15 pounds of wheat flour are used along with the yolks of 50 eggs. After having warmed the alum bath through which the skins have been passed, the flour is dusted into it, with careful stirring. The paste is well kneaded by the gradual addition of the solution, and passed through the cullender, whereby it becomes as clear as honey. To this the yolks being added, the whole is incorporated with much manual labor. The skins are worked one after another in this paste; and afterwards the whole together are left immersed in it for a day. They are now stretched and dried upon poles, in a proper apartment, during from 8 to 15 days, according to the season.

The effects of the paste are to whiten the skins, to soften them, and to protect them from the hardening influence of the atmosphere, which would naturally render them brittle. They would not bear working upon the *softening iron*, but for the emulsion which has been introduced into their substance. With this view they are dipped in a tub of clear water during five or six minutes, and then spread and worked upon the board. They are increased by this means in length, in the proportion of 5 to 3. No hard points must be left in them. The whiteness is also better brought out by this operation, which is performed upon the flesh side. The softening tool is an iron plate, about one foot broad, rounded over above, mounted upon an upright beam, 30 inches high, which is fixed to the end of a strong horizontal plank, 3½ feet long, and 1 broad. This plank is heavily loaded, to make it immovable upon the floor. Sometimes the skins are next spread over an undressed clean skin upon the horse, and worked well with the two-handled knife, for the purpose of removing the first and second epidermis, called the *fleur* and *arrière-fleur* by the French *megissiers*. They are then dried while stretched by hooks and strings. When dry they are worked on the *stretching iron*, or they are occasionally polished with pumice stone. A delicate yellow tint is given by a composition made of two parts of whitening, and one of ochre, applied in a moistened state, and well worked in upon the grain side. After being polished with pumice, they are smoothed with a hot iron, as the laundresses do linen, whereby they acquire a degree of lustre, and are ready to be delivered to the *glover*.

For *housings*, the best sheepskins are selected, and such as are covered with the longest and most beautiful fleece. They are steeped in water, in order to be cleansed and softened; after which they are thinned inside by the fleshing knife. They are now steeped in an old bran pit for 3 or 4 days, when they are taken out and washed. They are next subjected to the white or alum bath, the wool being carefully folded within; about 18 pounds of alum being used for 100 skins. The paste is made as for the fleeced skins, but it is merely spread upon their flesh side, and left upon them for 18 hours, so as to stiffen. They are then hung up to dry. They are next moistened by sprinkling cold water upon them, folded up, piled in a heap, and covered with boards weighted with heavy stones; in which state they remain for two days. They are next opened with a round iron upon the horse, and subjected to the stretching iron, being worked broadwise. They are dried with the fleece outermost, in the sun if possible; and are finished upon the *stretcher*.

Calf and lamb skins with their hair and wool are worked nearly in the same manner; only the thicker the skin, the stronger the alum bath ought to be. One pound of alum and one of salt are required for a single calf skin. It is left four days in this bath, after which it is worked upon the *stretcher*, then felled; when half dry the skins are opened upon the horse. In eight days of ordinary weather, they may be completely dressed. Lamb skins are sometimes steeped during eight days in a bath prepared with unbolted rye flour and cold water, in which they are daily moved about two or three times. They are then dried, stretched upon the iron, and switched upon the fleece side.

Chamois or Shamoy leather.—The skins are first washed, limed, felled, and branned as above described. They are next *efflowered*, that is, deprived of their epidermis by a concave knife, blunt in its middle part, upon the convex horse-beam. The cutting part serves to remove all excrescences, and to equalize the thickness, while the blunt part softens and smooths. The skins of goats, does, and chamois, are always treated in this way. They are next subjected to the fermenting bran steep for one or two days, in ordinary weather; but in hot weather for a much shorter time, sometimes only moving them in the sour bran liquor for a few minutes. They are lastly wrung at the peg, and subjected to the tulling mill.

When the skins have been sufficiently swelled and supplied by the branning, they may receive the first oil as follows: a dozen skins being stretched upon the table, the fingers are dipped in the oil, and shaken over the skins in different places, so as to impart enough of it to imbue the whole surface slightly, by friction with the palms of the hands. It is to the outside or *grain* that the oil is applied. The skins are folded four together, so as to form balls of the size of a hog's bladder, and thrown into the trough

of the fulling mill, to the number of twelve dozen at once. Here they remain exposed to the beater for two, three, or four hours, according to their nature and the state of the weather. They are taken out, aired, oiled, and again fullled. The airing and fulling are repeated several times, with more or less frequent oilings. Any cheap animal oil is employed.

After these operations, the skins require to be subjected to a fermenting process, to dilate their pores, and to facilitate their combination with the oil. This is performed in a chamber only 6 feet high, and 10 or 12 feet square. Poles are suspended horizontally a few inches from the ceiling, with hooks fixed in them to which the skins are attached. A somewhat elevated temperature is maintained, and by a stove if need be. This operation requires great skill and experience.

The remainder of the epidermis is next removed by a blunt concave knife and the horse; whereby the surface is not cut, but rather forcibly scraped.

The skins are now scoured to carry off the redundant oil; which is effected by a potash ley, at two degrees Baumé, heated no hotter than the hand can bear. In this they are stirred briskly, steeped for an hour, and lastly wrung at the peg. The soapy liquor thus expelled is used for inferior purposes. The clean skins, after being dried, are finished first on the *stretcher-iron*, and then on the *herse* or stretching frame.

Leather of Hungary.—This is manufactured by impregnating strong hides with alum, common salt, and suet; by a rapid process which is usually completed in the space of two months. The workshop is divided into two parts: 1. A shed on the side of a stream, furnished with wooden horses, fleshing knives, and other small tools. In one corner is a furnace with a boiler for dissolving the alum, a vat for immersing the hides in the solution, and several subsidiary tubs. 2. A chamber, 6 feet high, by 15 feet square, capable of being made very tight, for preserving the heat. In one corner is a copper boiler, of sufficient size to contain 170 pounds of tallow. In the middle of the stove is a square stone slab, upon which an iron grate is placed about a yard square. This is covered with charcoal. At each side of the stove are large tables, which occupy its whole length, and on which the leather is spread to receive the grease. The upper part below the ceiling is filled with poles for hanging the leather upon to be heated. The door is made to shut perfectly close.

The first operations are analogous to those of tanning and tawing; the skins being washed, cut in halves, shaved, and steeped for 24 hours in the river. They are then cleaned with 5 or 6 pounds of alum, and $3\frac{1}{2}$ pounds of salt, for a piece of hide which weighs from 70 to 80 pounds. The common salt softens the effect of the alum, attracts the moisture of the air, and preserves the suppleness of the skin. When the alum and salt are dissolved, hot water is poured upon the hides placed in a vat, and they are tramped upon by a workman walking repeatedly from one end of the vat to the other. They are then transferred into a similar vat containing some hot water, and similarly tramped upon. They are next steeped for eight days in alum water. The same round of operations is repeated a second time.

The skins are now dried either in the air, or a stove room; but before being quite dry, they are doubled together, well stretched to take out the wrinkles, and piled up. When dry, they are again tramped to open the pores as well as to render the skin pliant, after which they are whitened by exposure to the sun.

Tallow of inferior quality is employed for greasing the leather. With this view the hides are hung upon the poles in the close stove room, then laid upon the table, and besmeared with the tallow melted till it begins to crackle. This piece is laid on another table, is there covered with a second, similarly greased, and so forth. Three pounds of fat are commonly employed for one piece of leather.

When the thirty strips, or fifteen hides passed through the grease in one operation are completed, two workmen take the first piece in their hands, and stretch it over the burning charcoal on the grate for a minute, with the flesh side to the fire. The rest are passed over the flame in like manner. After *flaming*, the pieces are successively laid on an inclined table exposed to the fire, where they are covered with a cloth. They are finally hung upon poles in the air to dry; and if the weather be warm, they are suspended only during the night, so as to favor the hardening of the grease. Instead of the alum bath, M. Curaudan has employed with advantage a steep of dilute sulphuric acid.

Russian leather.—The Russians have long been possessed of a method of making a peculiar leather called by them *juten*, dyed red with the aromatic saunders wood. This article has been much sought after, on account of not being subject to mould in damp situations, being proof against insects, and even repelling them from the vicinity of its odor. The skins are freed from the hair or fleece, by steeping in an ash-lye too weak to act upon the animal fibres. They are then rinsed, fullled for a longer or shorter time according to their nature, and fermented in a proper steep, after having been washed in hot water. They are taken out at the end of a week, but they may be steeped

a second time it deemed necessary, to open their pores. They are now cleaned by working them at the horse on both the flesh and grain sides.

A paste is next composed, for 200 skins, of 38 pounds of rye flour, which is set to ferment with leaven. This dough is worked up with a sufficient quantity of water to form a bath for the skins, in which they are soaked for 48 hours; they are then transferred into small tubs, where they remain during fifteen days, after which they are washed at the river. These operations serve to prepare the skins for absorbing the astringent juices with uniformity. A decoction of willow bark (*salix cinerea* and *salix caprea*) being made, the skins are immersed in the boiler whenever the temperature of the liquor is sufficiently lowered not to injure the animal fibres, and handled and pressed for half an hour. This manipulation is repeated twice daily during the period of a week. The tanning infusion is then renewed, and applied to the same skins for another week; after which, being exposed to the air to dry, they are ready for being dyed, and then carried with the empyreumatic oil of the bark of the birch tree. To this substance the Russia leather owes its peculiarities. Many modes have been prescribed for preparing it; but the following is the one practised in Russia.

The whitish membranous epidermis of the birch, stripped of all woody parts, is introduced into an iron boiler, which, when stuffed full, is covered tight with a vaulted iron lid, having a pipe rising from its centre. A second boiler into which this pipe passes without reaching its bottom, is set over the first, and is luted to it at the edges, after the two are bolted together. They are then inverted, so that the upper one contains the birch bark. The under half of this apparatus is sunk in the earth, the surface of the upper boiler is coated over with a clay lute, then surrounded with a fire of wood, and exposed to a red heat, till the distillation be completed. This operation, though rude in appearance, and wasteful of wood, answers its purpose perfectly well. The iron cylinder apparatus used in Britain for distilling wood vinegar, would, however, be much more convenient and productive. When the above boilers are unluted, there is found in the upper one a very light powder of charcoal, and in the under one which served as a receiver, there is an oily, brown, empyreumatic fluid, of a very strong smell, which is mixed with the tar, and which floats over a small quantity of crude vinegar. The former matter is the oil employed to impregnate the skins, by working it into the flesh side with the currier's tools. It is difficult to make this oil penetrate with uniformity; and the Russians do not always succeed in this process, for they turn out many skins in a spotted state. This oil is at present obtained in France by distilling the birch bark in copper stills, and condensing the products by means of a pipe plunged in cold water. About 60 per cent. of the weight of the bark is extracted.

The skins imbibe this oil most equally before they are fully dry. Care must be taken not to apply too much of it, for fear of its passing through and staining the grain side of the leather. Chevreul has investigated the chemical nature of this odiferous substance, and finding it to be a peculiar compound, has called it *betuline*.

In the Franklin Institute for February, 1843, Mr. Gideon Lee has published some judicious observations on the process of tanning. He believes that much of the original gelatine of the hides is never combined with the tannin, but is wasted; for he thinks that 100 lbs. of perfectly dry hide, when cleaned from extraneous matter, should, on chemical principles, afford at least 180 lbs. of leather. The usual preparation of the hide for tanning he believes to be a wasteful process. In the liming and bating, or the unhairing and the cleansing, the general plan is first to steep the hides in milk of lime for one, two, or three weeks, according to the weather and texture of the skin, until the hair and epidermis be so loosened as to be readily removed by rubbing down, by means of a knife, upon a beam or block. Another mode is to suspend the hides in a close chamber, heated slightly by a smouldering fire, till the epidermis gets loosened by incipient putrefaction. A third process, called sweating, used in Germany, consists in laying the hides in a pack or pile, covered with tan, to promote fermentative heat, and to loosen the epidermis and hairs. These plans, especially the two latter, are apt to injure the quality of the hides.

The *bate*, consists in steeping the haired hides in a solution of pigeon's dung, containing, Mr. Lee says, muriate of ammonia, muriate of soda, &c.; but most probably phosphates of ammonia and lime, with urate of ammonia, and very fermentable animal matter. The dry hides are often subjected first of all to the operation of the fulling-stocks, which opens the pores, but at the same time prepares them for the action of the liming and bate; as also for the introduction of the tanning matter. When the fulling is too violent, the leather is apt to be too limber and thin. Mr. Lee conceives that the liming is injurious, by carrying off more or less of the gelatine and albumen of the skin. High-limed leather is loose, weighs light, and wears out quickly. The subsequent fermentation in the bating aggravates that evil. Another process has therefore been adopted in New York, Maine, New Hampshire, and some parts of Philadelphia, called, but incorrectly, *cool sweating*, which consists in suspending the hides in a

subterranean vault, in a temperature of 50° Fahr., kept perfectly damp, by the trickling of cold spring water from points in the roof. The hides being first soaked, are suspended in this vault from 6 to 12 days, when the hair is well loosened, by the mere softening effect of moisture, without fermentation.

LEATHER, MOROCCO. (*Maroquin*, Fr.; *Saffian*, Germ.) Morocco leather of the finer quality is made from goatskins tanned with sumach; inferior morocco leather from sheepskins. The goatskins as imported are covered with hair; to remove which they are soaked in water for a certain time, and they are then subjected to the operation called breaking, which consists in scraping them clean and smooth on the flesh side, and they are next steeped in lime-pits (milk of lime) for several days, during which period they are *drawn out*, with a hook, from time to time, laid on the side of the pit to drain, and replunged alternately, adding occasionally a little lime, whereby they are eventually deprived of their hair. When this has become sufficiently loose, the skins are taken out one by one, laid on convex beams, the work-benches, which stand in an inclined position, resting on a stool at their upper end, at a height convenient for the workman's breast, who scrapes off the hair with a concave steel blade or knife, having a handle at each end. When unhaired, the skins are once more soaked in milk of lime for a few days, and then scraped on the flesh side to render it very even. For removing the lime which obstructs their pores, and would impede the tanning process, as well as to open these pores, the skins are steeped in a warm semi-putrid alkaline liquor, made with pigeons' and hens' dung diffused in water. Probably some very weak acid, such as fermented bran-water, would answer as well, and not be so offensive to the workmen. (In Germany the skins are first washed in a barrel by a revolving axle and discs.) They are again scraped, and then sewed into bags, the grain outermost, like bladders, leaving a small orifice, into which the neck of a funnel is inserted, and through which is poured a certain quantity of a strong infusion of the sumach; and they are now rendered tight round the orifices, after being filled out with air, like a blown bladder. A parcel of these inflated skins are thrown into a very large tub, containing a weaker infusion of sumach, where they are rolled about in the midst of the liquor, to cause the infusion within to act upon their whole surface, as well as to expose their outsides uniformly to the tanning action of the bath. After a while these bladder-skins are taken out of the bath, and piled over each other upon a wooden rack, whereby they undergo such pressure as to force the enclosed infusion to penetrate through their pores, and to bring the tannin of the sumach into intimate contact, and to form a chemical combination with the skin fibres. The tanning is completed by a repetition of the process, of introducing some infusion or decoction into them, blowing them up, and floating them with agitation in the bath. In this way goatskins may be well tanned in the course of one day.

The bags are next undone by removing the sewing, the tanned skins are scraped as before on the currier's bench, and hung up in the drying loft or shed; they are said now to be "in the crust." They are again moistened and smoothed with a rubbing-tool before being subjected to the dyeing operations, in which two skins are applied face to face to confine the dye to one of their surfaces only, for the sake of economizing the dyeing materials which may be of several different colors. The dyed skins are grained by being strongly rubbed with a ball of box-wood, finely grooved on its surface.

Preparatory to being dyed, each skin is sewed together edgewise, with the grain on the outside, and it is then mordanted either with a solution of tin, or with alum water. The color is given by cochineal, of which from 10 to 12 ounces are required for a dozen of skins. The cochineal being boiled in water along with a little tartar or alum for a few minutes, forms a red liquor, which is filtered through a linen cloth, and put into a clean cask. The skins are immersed in this bath, and agitated in it for about half an hour; they are taken out and beaten, and then subjected to a second immersion in the cochineal bath. After being thus dyed, they are rinsed and tanned with Sicilian sumach, at the rate of two pounds for a skin of moderate size. This process is performed in a large tub made of white wood, in the liquor of which the skins are floated like so many bladders, and moved about by manual labor during four hours. They are then taken out, drained, and again subjected to the tanning liquor; the whole process requiring a space of twenty-four hours. The skins are now unstitched, rinsed, filled with beetles, drained, rubbed hard with a copper blade, and lastly hung up to dry.

Some manufacturers brighten the color by applying to the surface of the skins, in a damp state, a solution of carmine in ammonia with a sponge; others apply a decoction of saffron to enliven the scarlet tint. At Paris the morocco leather is tanned by agitation with a decoction of sumach in large casks made to revolve upon a horizontal axis, like a barrel churn. White galls are sometimes substituted for sumach; a pound being used for a skin. The skins must be finally cleaned with the utmost care.

The black dye is given by applying with the brush a solution of red acetate of iron to the grain side. Blue is communicated by the common cold indigo vat; violets, with a

light blue followed by cochineal red; green, by Saxon blue followed by a yellow dye, usually made with the chopped roots of the barberry. This plant serves also for yellows. To dye olive, the skins are first passed through a weak solution of green vitriol, and then through the decoction of barberry root, containing a little Saxon blue. Puce color is communicated by logwood with a little alum; which may be modified by the addition of a little Brazil wood. In all these cases whenever these skins are dyed, they should be rinsed, wrung, or rather drained, stretched upon a table, then besmeared on the grain side with a film of linseed oil applied by means of a sponge in order to promote their glossiness when curried, and to prevent them becoming horny by too rapid drying.

The last process in preparing morocco leather is the currying, which brings out the lustre, and restores the original suppleness. This operation is practised in different manners, according to the purpose the skins are to serve. For pocket-books, portfolios, and case-making in general, they must be thinned as much as possible upon the flesh side, moistened slightly, then stretched upon the table, to smooth them; dried again, moistened, and lastly passed two or three times through the cylinder press in different directions, to produce the crossing of the grain. The skins intended for the shoemaker, the saddler, the bookbinder, &c., require more pliancy, and must be differently curried. After being thinned, they are glazed with a polisher while still moist, and a grain is formed upon the flesh side with the roughened lead plate or grainer of the curriers, called in French *pommelle*; they are glazed anew to remove the roughness produced by the pommel, and finally grained on the flesh side with a surface of cork applied under a pommel of white wood.

TAWING OF SKINS. (*Mégisserie*, Fr.; *Weissgerberei*, Germ.) The kid, sheep, and lamb skins, are cleansed as has been described under leather in the Dictionary. In some factories they receive the tanning power of the submuriate of alumina (from a solution of alum and common salt) in a large barrel-churn apparatus; in which they are subjected to violent agitation, and thereby take the *aluming* in the course of a few minutes. In other cases, where the yolks of eggs are added to the above solution, the mixture, with the skins, is put into a large tub, and the whole trampled strongly by the naked feet of the operator, till the emulsion of the egg be forced into the pores of the skin. The tawed skins, when dry, are "staked," that is, stretched, scraped, and smoothed, by friction against the blunt edge of a semicircular knife, fixed to the top of a short beam of wood set upright. The workman holding the extremities of the skin with both hands, pulls it in all directions forcibly, but skilfully, against the smoothing "stake."

In an entertaining article on tanning in the 11th volume of the Penny Magazine, at page 215, the following description is given of one of the great tawing establishments of London:—

"In the production of 'imitation' kid leather, the skin of lambs is employed; and for this purpose lambskins are imported from the shores of the Mediterranean. They are imported with the wool yet on them; and as this wool is valuable, the leather-manufacturer removes this before the operations on the pelt commence. The wool is of a quality that would be greatly injured by the contact of lime, and therefore a kind of natural fermentation is brought about as a means of loosening the wool from the pelt. At the *Neckinger* establishment of Messrs. Bevington and Co., Bermondsey, one of the buildings presents, on the ground floor, a flight of stone steps, leading down to a range of subterranean vaults or close rooms, into which the lambskins are introduced in a wet state, after having been steeped in water, 'broken' on the flesh side, and drained. The temperature of these rooms is nearly the same all the year round, a result obtained by having them excluded as much as possible from the variations of the external atmosphere; and the result is that the skins undergo a kind of putrefactive or fermenting process, by which the wool becomes loosened from the pelt. During this chemical change ammonia is evolved in great abundance; the odor is strong and disagreeable; a lighted candle, if introduced, would be instantly extinguished, and injurious effects would be perceived by a person remaining long in one of the rooms. Each room is about ten feet square, and is provided with nails and bars whereon to hang the lambskins. The doors from all the rooms open into one common passage or vault, and are kept close, except when the skins are inspected. It is a point of much nicety to determine when the fermentation has proceeded to such an extent as to loosen the wool from the pelt; for if it be allowed to proceed beyond that stage, the pelt itself would become injured."

When the fermentation is completed, generally in about five days, the skins are removed to a beam, and there 'slimed'—that is, scraped on the flesh side, to remove a slimy substance which exudes from the pores. The wool is then taken off, cleaned, and sold to the hatters, for making the bodies of common hats. The stripped pelts are steeped in lime-water for about a week, to kill the grease; and are next "fleshed on the beam." After being placed in a "drench," or a solution of sour bran for some days to

remove the lime and open the pores, the skins are alumed, and subjected to nearly the same processes as the true kidskins. (See LEATHER.) These Mediterranean lamb-skins do not in general measure more than about 20 inches by 12; and each one furnishes leather for two pairs of small gloves. These kinds of leather generally leave the leather-dresser in a white state; but undergo a process of dyeing, softening, "stroking," &c., before being cut up into gloves.

The tanning of one average-sized skin requires about $1\frac{1}{2}$ lbs. of good Sicilian sumach; but for leather which is to receive a bright scarlet dye, from one half to three quarters of a pound of gall-nuts are employed in preference. Inferior goatskins are tanned with a willow-bark infusion, in pits, in which they are turned repeatedly, and laid out to drain, as in tanning sole-leather. The finest skins for the brightest scarlet are cured with salt, to prevent their receiving damage in the transport, and are dyed before being tanned. This method is practised in Germany and France.

Leather of deer and sheep-skins is prepared with oil, for the purpose of making breeches, &c., and for wash-leather, used in cleaning plate. After they are completely washed, limed, and beamed, as above described, they have their "grain"-surface removed, to give them greater softness and pliability. This removal of the grain is called "frizing," and it is done either with the round edge of a blunt knife, or with pumice-stone. After being freed from the lime by steeping in fermented bran-water, they are pressed as dry as may be, and are then impregnated with cod-oil, by beating with stocks in the trough of a kind of fulling-mill. Previously to the application of the oil, they are usually beat for some time alone to open their substance. The oiled skins are stretched, hung up for some time in the air, then fulled with oil as before—a process which is 8 or 9 times repeated. The oil is slowly and evenly poured upon the skins in the trough, during the action of the beaters. One hundred skins usually take up in this way from two to three gallons of oil. The fulled oiled skins are thrown into large tubs, and left for some time to ferment, and thereby to combine more intimately with the oil. They are lastly subjected to a weak potash ley bath, to strip them of the loosely adhering oil. They are then hung up in the air to dry, and dressed for the market.

The quantity of hides and skins converted into leather yearly in England is almost incredibly large. At Messrs. Bevington's establishment alone there are about 250,000 skins annually converted into leather by the aluming or tawing process; 220,000 by the sumach tanning process; as also a small number by the oil-dressing process. For the importation and exportation of skins, untanned and tanned, see *Hides*.

Leather and Skins in the Exhibition.—The present class includes a variety of manufacturing processes relating to the commercial preparation of animal substances in the form of leather, skins, fur, hair, and feathers. Until within a recent period, experience rather than science has directed the labors of manufacturers in their operations upon these substances. And at present the rules taught by experience are, in many cases, still pursued in practice, with, however, such modifications as an intelligent comprehension of the operations of the chemical and other philosophical laws put into force in the processes would suggest.

The following sub-classes are recognized in this class; a, leather, as rough and tanned, curried, enamelled, dyed; oil-leather, as buckskin, doeskin, &c.; white and alum leather; sheep and skin rugs, parchment and vellum; n, saddlery, and harness; c, miscellaneous; d, shink and furs of all descriptions for personal and domestic use; e, feathers, as those of ostrich, marabout, &c.; f, hair, ornamentally and usefully applied.

The localities in which the manufactures concerned in this class are carried on, and from whence articles for exhibition have chiefly been derived, are Bermondsey, where the preparation of leather has been successfully conducted during a very long period, Hull, Swansea, Bristol, Cork, Liverpool, Edinburgh, and Falmouth.

The manufacture of leather has been estimated as only fourth in importance among the national manufactures of Great Britain. A large amount of capital is employed in its production, and the number of artisans and others directly supported by this branch of industry has been taken to amount to nearly a quarter of a million. The total annual value of the leather manufactures is computed at about fourteen millions sterling. It appears probable that in the mere article of boots and shoes, upwards of seven millions sterling are annually expended by the inhabitants of this country. If it be considered that rather more than half the leather produced is thus applied, the remainder is employed in the production of harness, saddlery, gloves, and the multifarious purposes for which leather is applicable. Of late, chemistry has been studied attentively by those dependent upon this branch of industry, and successful results have ensued. A variety of patent processes exist by which the enormous amount of time involved in tanning on the old system is abridged to a surprising extent. With some specimens of leather it has not been unusual to devote eighteen months or upwards to their combination with the native principles of the bark. A few weeks are sufficient, under several of the new

systems to effect the same object. But it is stated that the leather produced rapidly differs from that produced by the slower process of combination in its durability and solidity. And it is considered by some, that time is an essential element in the manufacture, and that it cannot be advantageously shortened to any considerable extent.

Leather is unquestionably a chemical compound, and this renders it probable that a slow and gradual process of combination between the gelatine of the skin and the tannic acid of the bark may produce a leather to some extent of different properties to that formed by a quicker operation. A very large amount of leather is, however, manufactured by the rapid process, from which it may be concluded that the product possesses great commercial value. A great variety of leathers in all conditions and states of manufacture is exhibited, with instructive series illustrating the peculiarities of different methods of manufacture, according to the difference of the purposes for which the prepared skin is to be afterwards applied.

An extensive and interesting collection of furs is exhibited. Probably the opportunity has never before presented itself for a complete study of this class of manufacture. Furs of the most rare description, devoted only to the use of monarchs, are among these specimens. To the naturalist desirous of ascertaining the genera and species yielding the furs of commerce—a subject on which much conflicting opinion exists—these objects, which are fully and correctly described in the catalogue of this class, will be highly interesting and instructive. Feathers and hair are also represented by various interesting objects, possessing their peculiar merits and attraction. The number of exhibitors in this class is considerable; but since it includes boots and shoes, and other articles of personal and domestic use in addition to saddlery, &c., the number of persons actually appearing in the capacity of manufacturers is to be distinguished from the proprietors. And, as is the common rule, the class of producers or manufacturers bears only a small proportion to that of proprietors, or, in the commercial sense, vendors of manufactured articles.

Hudson's Bay Company, producers.—Specimens of skins from the Arctic regions, belonging to the Hudson's Bay Company, selected for the Exhibition from their importation of 1851, prepared and arranged by the exhibitors from No. 1. to No. 27.

The immense tracts of country over which the Hudson's Bay Company has control may be considered as vast hunting-grounds, affording a varied and exhaustless supply of furs. The territorial possessions of this Company cover nearly one-eighth of the habitable globe. Russia is next in order and importance in this respect, but with a different race of animals. The fur produce of North America and the Canadas is also important. As we approach the tropics and the warmer regions, the silky fur with which the animals are clothed in the northern climes disappears, and fur of a totally different character is met with, which, although splendid in appearance, is not adapted for warmth or general use.

TABLE OF IMPORTS AND EXPORTS.

	Total Importation into England.	Exported.	Consumed in England.
Raccoon - - - -	525,000	525,000	none
Beaver - - - -	60,000	12,000	48,000
Chinchilla - - - -	85,000	30,000	55,000

1. Group of black and silver furs (*Vulpis pelvis*, var. *argentatus*).
2. Group of foxes (*Vulpis fulvis*, var. *decussatus*).
3. Group of red and silver foxes (*Vulpis fulvis*).
4. " white " (*Vulpis lagopus*).
5. " kitt " (*Vulpis velox*).

The black and silver fox is the most valuable of his tribe; they are generally purchased for the Russian and Chinese markets, being highly prized in those countries. The cross and red fox are used by the Chinese, Greeks, Persians, &c., for cloak-linings and for trimming dresses. The white and blue fox is used in this and other countries for ladies' wear. In the sumptuary laws passed in the reign of Henry III., the fox is named with other furs then in use.

7. Group of beaver (*Castor Americanus*).

The beaver in former years was one of the Hudson's Bay Company's most valuable productions; but since its use has been almost entirely discontinued in the manufacture of hats, it has lost much of its value. Experiments have, however, been made, and with prospect of success, to adapt its fine and silky wool to weaving purposes. The skin of the beaver is prepared by a new process, after which the surface is cut by a new and ingenious machine, and the result is a beautiful fur for ladies wear. It is exported in its prepared state to various parts of Europe and the East.

The rich white wool from the under part of the beaver is largely exported to France.

8. Group of lynx (*Felis Canadensis*).

9. " lynx cat (*Felis rufa*).

Both the above furs, when dyed, were formerly much used. It is still dyed and prepared, and exported in large numbers for the American market. In its natural state, it is a grayish white, with dark spots and is used by the Chinese, Greeks, Persians, and others, for cloaks, lining, facings, &c.; it is very soft, warm, and light. The fur formerly called the lucern is the lynx.

21. Group of black bear (*Ursus Americanus*).

22. " brown bear (*Ursus*, var. *Americanus*).

23. " gray bear (*Ursus ferox*).

The large North American black bear is technically termed the army bear, because it is generally used for military purposes in this and other countries, for caps, pistol-holders, rugs, carriage hammer-cloths, sleigh-coverings, &c. The fine black cub bears are much sought after in Russia for making shube-linings, coat-linings, trimmings, facings, &c. The other sorts with the large gray bears, for sleigh-coverings, and accompaniments, &c. The white polar bear, the supply of which is very limited, is generally made into rugs, which are often bordered with the black and gray bear. The brown or Isabella is at the present time used for ladies' wear in America.

301a. *Nicholay, John Aug., & Son*, 82 Oxford-street. Collectors, Importers, Manufacturers, &c. Selected from Canadian importation, with the assistance of C. M. Lampson, Esq.

28. Group of racoon (*Procyon lator*).

The finest racoon furs are produced in North America, and are imported into this country in immense numbers. They are purchased here by the merchants who attend the periodical fur sales, and who dispose of large quantities at the great fair at Leipsic; they are principally used in Russia and throughout Germany, for lining shubes and coats, and are exclusively confined to gentlemen's wear. The dark skins are the choicest and are very valuable.

64. Group of seal, (*Phoca*), Georgia, Shetland Isles, Falkland Isles, Lomar's Island, and Cape.

65. " plucked and prepared seal, natural color.

66. " plucked and prepared seal, dyed.

67. " Greenland and Newfoundland seal.

68. " Greenland and Newfoundland seal, dyed.

69. " spotted and silver seal.

The seal is an inhabitant of most countries; it is found in the high northern latitudes in immense numbers; ships are purposely fitted for its capture; the oil produced by the animal, together with its skin, render it (connected as it is with the whale fishery)

important to the trader and interesting to the naturalist. The skins are salted and packed in casks, in which state they are sent to this country; they are then sorted and selected for various purposes; those suitable for leather pass into the tanners' hands, and make a beautiful leather, which is used for ladies' shoes. The blue back, the hair and the silver seal are dressed and used in their natural state, and also dyed and exported in large quantities. The fur seal, the supply of which is always small compared with the other kinds, undergoes a process to prepare it for its intended use. It is brought at the present time to a great degree of perfection in this country: when divested of the long, coarse hair (which protects it in its native element) there remains the rich, curly, silky, yellowish down, in which state it was formerly used for travelling caps and other purposes. It is now seldom made use of in that state, but dyed a beautiful Vandyke brown, giving it the appearance of the richest velvet, and is manufactured in every variety of shape and form, as articles of dress for ladies', gentlemen's and children's wear.

South American.—70. Group of chinchilla, Buenos Ayres (*Chinchilla lanigera*).

71. Group of chinchilla, Arica (*Chinchilla lanigera*).

72. Group of bastard chinchilla or Lima (*Chinchilla lanigera*).

The chinchilla is exclusively a South American animal, and was introduced into this country and France about forty years since.

Group of ermine (*Mustela erminea*).

The ermine is produced in most countries, but the best is from Russia, Sweden, and Norway, and is killed in winter when the fur is pure white (except the tail, with its jet black tip), it being in that season in its greatest perfection; in summer and spring it is gray, and of little or no value. It is the weasel of more southern climes. The ermine is the royal fur of Russia, Germany, Spain, Portugal, Italy, &c. In England at the coronation of the sovereign, the minever, as the ermine is styled in heraldic language, is used, being powdered, that is studded with black spots. The spots or powdered bars on the minever capes of the peers and peeresses being in rows, and the number of rows or bars denoting their various degrees of rank; the sovereign alone and the blood royal having the minever of the coronation robes powdered all over, a black spot being inserted in about every square inch of the fur, crimson velvet being used on that occasion. The crown is also adorned with a band of minever, with a single row of spots; the coronets of the peers and peeresses having a similar arrangement. The black spots are made of the black Astracan lamb. On state occasions in the House of Lords, the peers are arrayed in their robes of state, of scarlet cloth and gold lace, with bars or rows of pure minever, more or less according to their degrees of rank, the sovereign alone wearing the royal minever powdered all over. The judges in their robes of office are clad in scarlet and pure ermine. The ermine, with the tail of the animal inserted therein, is used as articles of dress for ladies in every variety of shape and form, according to the dictates of fashion, and also as cloak linings.

The minever can only be worn on state occasions by those who by their rank are entitled to its use, but as an article of fashion for ladies' wear there is no prohibition in force. In the reign of Edward III., furs of ermine were strictly forbidden to be worn by any but the royal family, and its general use is prohibited in Austria at the present time. In mercantile transactions, ermine is always sold by the timber, which consists of forty skins. The minever fur of a former era was the white belly of the gray squirrel.

36. Group of kolinski (*Mustela Sibirica*).

The kolinski or Tartar sable is produced from Russia, belongs to the weasel tribe, and is in color a bright yellow; it is much used in its natural state and also dyed to imitate the cheaper sables.

37. Group of squirrel, black (*Sciurus niger*).

38. " squirrel, blue (*Sciurus*, var. *niger*).

39. " squirrel, kasan (*Sciurus*, var. *Griscus*).

40. " squirrel, red (*Sciurus vulgaris*).

The squirrel abounds in Russia (where it is produced in the greatest perfection) in such immense numbers as would appear almost incredible: the importation from thence to this country alone last year exceeding 2,000,000. The celebrated Weisenfels lining is made from the white part of the dark blue squirrel. A full-sized cloak lining weighs only 25 ounces; it is known as the *petit gris*. For colder climates, the linings are made from the back or plain gray part of the squirrel, the best having part of the tail left on each skin. Russia produces about 23,000,000 annually.

41. Group of fitch or pole-cat (*Putorius fatidus*).

About 40 years since this fur was more largely used than at present. It is produced in the greatest perfection in this country.

42. Group of Crinca gray lamb.

43. " Ukraine black lamb.

44. Group of Astracan black lamb.

45. " Astracan gray lamb.

46. " Persian black lamb.

47. " Persian gray lamb.

48. " Spanish lamb.

49. " Hungarian lamb.

50. " English lamb.

The gray and black Persian lamb is mostly used for gentlemen's cloak and coat linings, for facings, collars, caps, &c., and also for army purposes. The Astracan lamb is a rich, wavy, glossy, black skin, very short in the fur, having the appearance of beautiful watered silk: in order to obtain this choice skin, it is averred that the parent sheep is destroyed a certain time before the birth of the lamb. The Persian gray and black lamb is covered with very minute curls; this is produced, it is said, by the animal being as soon as born sewn up tightly in a leathern skin, which prevents the curl expanding. The Hungarian lamb is produced in that country in immense numbers; of it the national coat, called the Juhasz Bunda, is made. In the summer or wet weather the fur or woolly part is worn outside; in winter, when warmth is required, it is reversed: the skin is tanned or dressed in a way peculiar to the country, and decorated and embroidered in accordance with the means and taste of the wearer. In Spain the lamb-skin is used for the well-known characteristic short jacket of that country, which is adorned with filigree silver buttons; the coarser kinds of both colors are used for our cavalry, and is also employed for mounting and bordering skins, as leopards, tigers, &c., for ornamental and domestic purposes. In the reign of Richard II., the sergeant-at-law wore a robe furred inside with white lambskin and a cape of the same.

51. Group of Perewartzki.

52. " Hamster.

The above are from Russia: the former is used by ladies; the latter is made into cloak linings, which are exceedingly light, durable, and cheap.

53. Group of colored cat.

54. " black cat.

55. " black Dutch.

56. " colored Dutch.

The cat, properly attended to and bred purposely for its skin, supplies a most useful and durable fur: in Holland it is bred and kept in a confined state till the fur is in its greatest perfection, and is fed entirely on fish. In other countries and especially in our own, it is produced in large numbers. The wild cat is much larger and longer in the fur, and is met with in extensive forests, particularly in Hungary: the color is gray, spotted with black, and its softness and durability render it suitable for cloak and coat linings, for which purposes it is much used. The black species is also much in request, and similarly used, and with the spotted and striped varieties, is made into wrappers for open carriages, sleigh coverings, and railway travelling.

92. Group of dyed lynx, see No. 8.

94. " penguin (*Spheniscus aptenodytes*).

95. " grebe (*Podiceps cristata*).

The grebe is an aquatic bird, inhabiting most of the large lakes in Europe. The choicest specimens are from Geneva, Italy, and Holland. The feathers are of rich white, having the appearance of polished silver, the plumage on the outer edge of the skin being a rich dark brown; it is used by ladies and forms a beautiful article of dress, and is worn as trimmings for the trains of court and drawing-room dresses, for muffs, cuffs, boas, &c. It is very durable; the exquisite smoothness of its feathers prevents its soiling with wear.

96. Specimen of swan feathers.

97. " goose feathers.

98. " eider down.

The bird from which the down is taken is found in large numbers in Iceland, Norway, Sweden, &c.; its color is dark gray, and its elasticity, lightness, and resistance to wet, are prominent amongst its other advantages: it is used for the inside stuffing of muffs. On the continent the well-known eider-down quilts are largely used.

99—115. Suits of Russia sable; Hudson's Bay sable; sable tail, mink; chinchilla; grebe; sea otter; Siberian squirrel, with tails; kolinski; minever; ermine; moleskin; natural beaver; dyed beaver; seal; swan; goose-down.

The down of the goose is manufactured by being sewn on textile fabrics. It is a specimen of Irish industry, and has been patronized and sold in England extensively for the benefit of the Irish female poor, by whom it has been made up. The price, compared with the true swan's down, is very moderate. Being sewn upon cloth, it can be washed.

LEATHER SPLITTING. This operation is employed sometimes upon certain

sorts of leather for gloves, for bookbinders, sheath-makers, and always to give a uniform thickness to the leather destined for the cotton and wool card-makers.

Figs. 863, 864, 865, 866, represent a well-contrived machine for that purpose, of which fig. 863 shows the front view, fig. 864 a view from the left side, fig. 866 a ground plan, and fig. 865 a vertical section across the machine. *a* is a strong table, furnished with four legs *b*, which to the right and left hand bears two horizontal pieces *c*. Each of

these pieces is cut out in front, so as to form in its substance a half-round fork, that receives a cylinder *d*, carrying on its end a toothed spur-wheel *e*. Motion is com-

municated to the wheel by means of the handle *f*, upon whose axis the pinion, *i*, is fixed, working into the wheel *d*, made fast to the end of the cylinder round which the leather is rolled. The leather is fixed at one of its ends or edges to the cylinder, either with a wedge pressed into a groove, or by a moveable segment of the cylinder itself.

The table, *a*, is cut out lengthwise with a slot, that is widened below, as shown in fig. 865.

The knife *h* (figs. 865 and 866) is fixed flat upon the table with screw bolts, whose

heads are countersunk into the table, and secured with taps beneath (*fig. 865*), the edge of the knife being placed horizontally over the opening, and parallel with it.

In *fig. 865*, the leather, *k*, is shown advancing against the knife, getting split, and has a portion coiled round the cylinder, which is made to revolve in proportion as the leather is cleft. The upper portion of the leather is rolled upon the cylinder *d*, while the under half, *l*, falls through the oblong opening upon the ground.

In regulating the thickness of the split leather, the two supports, *m*, act; they are made fast to the table *a* (one on each side of the knife), and are mortised into the table by two tenons secured beneath. These supports are furnished near their tops with keyed slots, by means of which the horizontal iron rod *o* (*figs. 863, 865*), is secured, and outside of the uprights they press upon the springs *p p*, which tend to raise the rod, *o*, in its two end slots; but the adjusting screws *q*, which pass down through the tops of the supports into the mortise *n* (*fig. 865*), and press upon the upper half of the divided tenon, counteract the springs, and accordingly keep the rod, *o*, exactly at any desired height or level. The iron rod, *o*, carries another iron bar, *r*, beneath it, parallel and also rectangular, *fig. 865*. This lower bar, which is rounded at its under face, lies upon and presses the leather, by the action of two screws, which pass through two upright pieces *s* (*figs. 863, and 865*), made fast to the table; thus the iron bar, *r*, may be made to press forwards the edge of the knife, and it may be adjusted in its degree of pressure, according to the desired thickness of the leaf of split leather, that passes through under it.

Fig. 865, shows that the slant or obliquity of the knife is directed downwards, over one of the edges of the oblong opening *g*; the other edge of this opening is provided with an iron plate *t* (*figs. 865, 866*), which serves to guide the blade in cutting the leather to the proper depth. For this purpose the plate is made adjustable by means of the four springs *u* (*figs. 865, 866*), let into the table, which press it downwards. Four screws, *v*, pass down through the table, each belonging to its respective springs *u*, and by means of these screws the plate, *t*, may be raised in any desired degree. Each of the screws, *u*, has besides a small rectangular notch through which a screw bolt, *x*, passes, by which the spring is made fast to the table. Thus also the plate, *t*, may be made to approach to or recede from the knife.

y, in *figs. 863, and 865*, is a flat board, laid upon the leather a little behind the edge of the plate *t*; this board is pressed by the cylinder *z*, that lies upon it, and whose tenons rest in mortises cut out in the two supports *a'*. The cylinder, *z*, is held in its position by a wedge or pin *b* (*figs. 863, and 864*), which passes through the supports. When the leather has been split, these pins are removed, and the cylinder rises then by means of the two counter weights, not shown in the figures.

The operation of the machine is as follows;—The edge or end of the leather being secured to the cylinder *d*, the leather itself having the direction upon the table shown in *fig. 865*, and the bar, *r*, its proper proportion over the knife, the edge begins to enter in this position into the leather, while the cylinder, *d*, is moved by the handle or winch, and the piece gets split betwixt the blade and the roller *d*. When the other end of the leather, *k*, advances to the knife, there is, consequently, one half of the leather split; the skin is to be then rolled off the cylinder *d*; it is turned; the already split half, or the end of the leather *k*, is made fast into the wood of the cylinder, and the other half is next split; while the knife now acts from below, in an opposite direction to what it did at first.

That the unrolling of the leather from the cylinder, *d*, may not be obstructed by the pinion *i*, the stop-wedge *e* (*figs. 863, 864*) is removed from the teeth. In the process of splitting, the grain side of the leather is uppermost, and is therefore cut of an uniform thickness, but the underside varies in thickness with the inequality of the skin.

The quantity of leather gloves of Foreign production exported in 1850, was 401,009 pairs, and in 1851, 107,925 pairs. See Hides.

LEDUM PELUSTRE. This plant is employed in Russia to tan the skin of goats, calves, and sheep, into a reddish leather of an agreeable smell; as also in the preparation of the oil of birch, for making what is commonly called Russia leather.

LEGUMINE, is the name of a vegeto-alkali supposed to exist in leguminous plants.

LEMONS. See CITRIC ACID, and OILS, ESSENTIAL.

LEVIGATION is the mechanical process whereby hard substances are reduced to a very fine powder.

LEUCITE is a hard Vesuvian mineral, consisting of silica, 54; alumina, 23; potash, 23.

LEUCINE is a white crystalline substance produced by acting upon flesh with sulphuric acid.

LEWIS is the name of one kind of shears used in cropping woollen cloth.

LIAS is a fine-grained argillaceous limestone, whose geological position is under the oolite; it is the proper lithographic stone.

LIBAVIUS, LIQUOR OF, is the bichloride of tin, prepared by dissolving that metal, with the aid of heat, in *aqua regia*, or by passing chlorine gas through a solution of muriate of tin till no more gas be absorbed, evaporating the solution, and setting it aside to crystallize. The anhydrous bichloride is best prepared by mixing four parts of corrosive sublimate with one part of tin, previously amalgamated with just so much mercury as to render it pulverizable; and by distilling this mixture with a gentle heat. A colorless fluid, the dry bichloride of tin, or the proper fuming liquor of Libavius, comes over. When it is mixed with one third of its weight of water it becomes solid. The first bichloride of tin is used in calico-printing.

LICHEN. See ARCHIL.

LIGNEOUS MATTER is vegetable fibre. See FIBROUS MATTER.

LIGNITE is one of the most recent geological formations, being the carbonaceous remains of forest trees. From this substance, as found in the neighborhood of Cologne, the brown colors, called *umber* and *earth of Cologne*, are prepared.

LILACH DYE. See CALICO-PRINTING AND DYEING.

LIMESTONE (*Calcaire*, Fr.; *Kalkstein*, Germ.), may be classed under the following heads:—

1. *Calcareous spar* occurs in colorless crystals or crystalline masses; dissolves with effervescence in muriatic acid; is scratched by soft iron, but not by the nail; specific gravity 2.7; loses 46 per cent. by the expulsion of carbonic acid, and calcines into quicklime.

2. *Calcsinter*, or *stalactitic carbonate of lime*, called also *concretionary limestone*, because formed of zones more or less undulated, and nearly parallel. These zones have a fibrous structure, arising from the successive deposits of the crystalline limestone from its solvent water. The long conical pieces called *stalactites*, show fibres converging to the axis. The tubercular consists of irregular lumps often sprinkled over with small crystals, and associated so as to exhibit the appearance of cauliflower. The stratiform, commonly called *stratagmite*, or *alabaster limestone*, represents zones not concentric, but spread out, waving, and parallel; its texture is sometimes lamellar, and sometimes fibrous. These waving strata are distinguishable from one another by their different densities, and by their degrees of translucency. This *stalagmitic* mass bears the name of *oriental alabaster*, when it is reddish-yellow with distinct zones, and is susceptible of a fine polish. *Stalactites* are formed in the large excavations of *calcareous* rocks. The water percolating down through them, and dropping from the roofs of the caverns, is usually charged with carbonate of lime held in suspension by an excess of carbonic acid. The exposure to air, the motion, and the consequent diminution of pressure, cause the precipitation of the carbonate of lime in the solid state. Each drop of water, on falling through the vault, abandons a small film of limestone, which enlarges by degrees, and forms either a cylinder or solid mass. This *alabaster* differs from *marble* in its parallel and waving layers, and its faint degree of transparency.

This *alabaster* serves for the decoration of public buildings, and is occasionally introduced into certain pieces of furniture. The fine Egyptian *alabaster* was anciently brought from the mountains of the Thebaid, between the Nile and the Red Sea, near a town called *Alabastron*, whence probably the name. Very fine red *alabaster*, of great hardness, was found at one time in the quarries of Montmartre, but the stock was soon exhausted.

The *incrusting concretionary limestone* differs little from the preceding except in the rapidity of its formation, and in being moulded upon some body whose shape it assumes. These deposits from *calcareous* springs, form equally on vegetable bodies, on stones, metals, within pipes of cast iron, wood, or lead. The incrustations on vegetable and animal substances are vulgarly called *petrifications*, as the organic fibres are replaced by stone. One of the most curious springs of this nature is at the baths of Saint Philip, in Tuscany, where the water flows in almost a boiling state, over an enormous mass of *alabaster* which it has produced. The carbonate of lime seems to be held in solution here by sulphureted hydrogen, which flies off when the water issues to the day. Dr. Vegny has taken advantage of this property of the spring, to obtain *basso-relievo* figures of great whiteness and solidity. He makes use of sulphur moulds.

Calcareous tuf consists of similar incrustations made by petrifying rivulets running over mud, sand, vegetable remains, &c. It is porous, even cellular, somewhat soft, impure, and of a dirty gray color. Its surface is wavy, rough, and irregular. These incrustations or deposits are, however, sometimes so abundant, and the resulting stony matters so hard that buildings may be constructed with them. The stone with which the town of Pasti, in Italy, is built has been called *pipe-stone* by the Italians; and it has apparently derived its origin from incrustations upon large reeds.

The *travertino*, which served to construct all the monuments of Rome, appears to have been formed by the deposits of the Anio and the solfatara of Tivoli. The temples of Pæstum, which are of extreme antiquity, have been built with a *travertino* formed by the sediment of the waters which still flow in this territory. All these stones acquire great hardness in the air, and M. de Breislak thinks that it is to the happy union of *travertino* and *pouzzolana* in the same spot, that the monuments of Rome owe their great solidity.

Spongy limestone, usually called *Agaric mineral*, stone marrow, &c., belongs to this kind of formation. It has a very white color, a very fine grain, is soft to the touch, very tender, and light enough to float for an instant on water. It occurs in rather thin layers, in the crevices of calcareous rocks, and is so common in Switzerland as to be employed for whitening houses.

3. *Compact limestone*, is of a grain more or less fine, does not polish, nor afford large blocks free from fissures, has a conchoidal, or uneven scaly fracture. Colors very various. Its varieties are; *a*, The *sub-lamellar*, compact, with some appearance of a foliated texture. *b*, *Compact fine-grained limestone*, the *zechstein* of the Germans, to which M. Brongniart refers the lithographic stone in his classification of rocks (*Dictionnaire des Sciences Naturelles*), but the English geologists place the locality of the famous lithographic quarry of Solenhofen much higher in the plane of secondary superposition. Its fracture is conchoidal; color from gray to whitish; *c*, *Compact common limestone*. Grain of middle size; earthy aspect; uneven fracture; perfectly opaque; color, whitish to pale gray, yellow, or reddish. The limestones of the Jura formation are referred to this head, as well as most of those interspersed among the coal strata. *d*, The *coarse compact*, or *Cornbrash*; texture somewhat open, earthy aspect, rough to the touch, ragged fracture, color yellow, gray, or dirty red. *e*, *Compact cellular*, the *Rauchkalk* and *Holekalk* of the Germans, on account of the numerous holes or caverns distributed through it.

4. *Oolite* or *roe-stone*.—It consists of spherical grains of various size, from a millet seed, to a pea, or even an egg; texture compact; fracture even; colors, whitish, yellow, gray, reddish, brownish. The larger balls have almost always a foreign body for their centre or nucleus.

5. *Chalk*; texture earthy; grains fine, tender, friable; colors white, grayish, or pale yellowish.

6. *Coarse-grained limestone*; an earthy texture, in large particles, often loose; fracture foliated, uneven; color pale and dirty yellow. Coarse *lias* has been referred to this head.

7. *Marly limestone*; lake and fresh water limestone formation; texture fine-grained, more or less dense; apt to crumble down in the air; color white or pale yellow; fracture rough-grained, sometimes conchoidal; somewhat tenacious. Texture occasionally cavernous; with cylindrical winding cavities. This true limestone must not be confounded with the lime-marl, composed of calcareous matter and clay.

8. *Silicious limestone*; of a compact texture; scratching steel, and scratched by it; leaves a silicious residuum after the action of muriatic acid.

9. *Calp*; texture compact; fine-grained; schistose structure; hard, as the preceding; not burning into quicklime, affording to dilute muriatic acid a copious residuum of clay and silica; color blackish; found in beds in the transition district near Dublin.

10. *Lucullite* or *stinkstone*; texture compact or sub-lamellar, color grayish; emits the smell of sulphureted hydrogen by friction or a blow. It occurs at Assynt, in Sutherlandshire; in Derbyshire; counties of Kilkenny, Cork, and Galway.

11. *Bituminous limestone*; black or blackish color; diffusing by the action of fire a bituminous odor, and becoming white.

Of all common limestones the purity may most readily be determined by the quantity of carbonic acid which is evolved during their solution in dilute nitric or muriatic acid. Perfect carbonate of lime loses in this way 46 per cent.; and if any particular limestone loses only 23 per cent., we may infer that it contains only one half its weight of calcareous carbonate. This method is equally applicable to *marls*, which are mixtures in various proportions of carbonate of lime, clay, and sand, and may all be recognised by their effervescing with acids.

The chief use of calcareous stones is for procuring quicklime by calcination in proper

furnaces; and they are all adapted to this purpose provided they are not mixed with too large a proportion of sand and ferruginous clay, whereby they acquire a vitrescent texture in a high heat, and will not burn into lime. Limestone used to be calcined in a very rude kiln, formed by enclosing a circular space of 10 or 15 feet diameter, by rude stone walls 4 or 5 feet high, and filling the cylindrical cavity with alternate layers of turf or coal and limestone broken into moderate pieces. A bed of brushwood was usually placed at the bottom, to facilitate the kindling of the kiln. Whenever the combustion was fairly commenced, the top, piled into a conical form, was covered in with sods, to render the calcination slow and regular. This method being found relatively inconvenient and ineffectual, was succeeded by a permanent kiln built of stones or brick-work, in the shape of a truncated cone with the narrow end undermost, and closed at bottom by an iron grate. Into this kiln, the fuel and limestone were introduced at the top in alternate layers, beginning of course with the former; and the charge was either allowed to burn out, when the lime was altogether removed at a door near the bottom, or the kiln was successively fed with fresh materials, in alternate beds, as the former supply sunk down by the calcination, while the thoroughly burnt lime at the bottom was successively raked out by a side door immediately above the grate. The interior of the lime kiln has been changed of late years from the conical to the elliptical form; and probably the best is that of an egg placed with its narrow end undermost, and truncated both above and below; the ground plot or bottom of the kiln being compressed so as to give an elliptical section, with an *eye* or draft-hole towards each end of that ellipse. A kiln thus arched in above gives a reverberatory heat to the upper materials, and also favors their falling freely down in proportion as the finished lime is raked out below; advantages which the conical form does not afford. The size of the draft-holes for extracting the quicklime, should be proportionate to the size of the kiln, in order to admit a sufficient current of air to ascend with the smoke and flame, which is found to facilitate the extrication of the carbonic acid. The kilns are called *perpetual*, because the operation is carried on continuously as long as the building lasts; and *draw-kilns*, from the mode of discharging them by raking out the lime into carts placed against the draft-holes. Three bushels of calcined limestone, or lime-shells, are produced on an average for every bushel of coals consumed. Such kilns should be built up against the face of a cliff, so that easy access may be gained to the mouth for charging, by making a sloping cart road to the top of the bank.

*Fig. 167, 868, 869, 870, represent the lime-kiln of Rüdersdorf near Berlin, upon the continuous plan, excellently constructed for economizing fuel. It is triple, and yields a threefold product. Fig. 869, is a view of it as seen from above; fig. 870, the elevation and general appearance of one side; fig. 867, a vertical section, and fig. 868, the ground plan in the line *a b c d* of fig. 867. The inner shaft *fig. 868*, has the form of two truncated cones, with their larger circular ends applied to each other; it has the greatest width at the level of the fire-door *b*, where it is 8 feet in diameter; it is narrower below at the discharge door, and at the top orifice, where it is about 6 feet in diameter. The interior wall *d*, of the upper shaft, is built with hewn stones to the height of 38 feet, and below that for 25 feet, with fire-bricks *d' d'*, laid stepwise. This inner wall is surrounded with a mantle *e*, of limestone, but between the two there is a small vacant space of a few inches filled with ashes, in order to allow of the expansion of the interior with heat taking place without shattering the mass of the building.*

The fire grate, *b*, consists of fire-tiles, which at the middle, where the single pieces press together, lie upon an arched support *f*. The fire-door is also arched, and is secured by fire-tiles. *g* is the iron door in front of that orifice. The tiles which form the grate have 3 or 4 slits of an inch wide for admitting the air, which enters through the canal *h*. The under part of the shaft from the fire to the hearth is 7 feet, and the outer enclosing wall is constructed of limestone, the lining being of fire-bricks. Here are the ash-pit *i*, the discharge outlet *a*, and the canal *k*, in front of the outlet. Each ash-pit is shut with an iron door, which is opened only when the space *i* becomes filled with ashes. These indeed are allowed to remain till they get cool enough to be removed without inconvenience.

The discharge outlets are also furnished with iron doors, which are opened only for taking out the lime, and are carefully luted with loam during the burning. The outer walls *l m n* of the kiln, are not essentially necessary, but convenient, because they afford room for the lime to lie in the lower floor, and the fuel in the second. The several stories are formed of groined arches *o*, and platforms *p*, covered over with limestone slabs. In the third and fourth stories the workmen lodge at night. See *fig. 870*. Some enter their apartments by the upper door *q*; others by the lower doors *s*. *r* is one of the chimneys for the several fire-places of the workmen. *t u v* are stairs.

As the limestone is introduced at top, the mouth of the kiln is surrounded with a strong iron balustrade to prevent the danger of the people tumbling in. The platform is laid with rails *w*, for the wagons of limestone, drawn by horses, to run upon. *x* is another rail-way, leading to another kiln. Such kilns are named after the number of their fire-doors, single, twofold, threefold, fourfold, &c.; from three to five being the most usual. The outer form of the kiln also is determined by the number of the furnaces; being a truncated pyramid of equal sides; and in the middle of each alternate side there is a fire-place, and a discharge outlet. A cubic foot of limestone requires for burning, one and five twelfths of a cubic foot of wood, and one and a half of turf.

When the kiln is to be set in action, it is filled with rough limestones, to the height *c d*, or to the level of the firing; a wood fire is kindled in *a*, and kept up till the lime is calcined. Upon this mass of quicklime, a fresh quantity of limestones is introduced, not thrown in at the mouth, but let down in buckets, till the kiln be quite full; while over the top a cone of limestones is piled up, about 4 feet high. A turf-fire is now kindled in the furnaces *b*. Whenever the upper stones are well calcined, the lime under the fire-level is taken out, the superior column falls in, a new cone is piled up, and the process goes on thus without interruption, and without the necessity of once putting a fire into *a*; for in the space *c b*, the lime must be always well calcined. The discharge of lime takes place every 12 hours, and it amounts at each time in a threefold kiln, to from 20 to 24 Prussian tonnes of 6 imperial bushels each; or to 130 bushels imperial upon the average. It is found by experience, that fresh-broken limestone which contains a little moisture, calcines more readily than what has been dried by exposure for some time to the air; in consequence of the vapor of water promoting the escape of the carbonic acid gas; a fact well exemplified in distilling essential oils, as oil of turpentine and naphtha, which come over with the steam of water, at upwards of 100 degrees F. below their natural term of ebullition. Six bushels of Rüdersdorf quicklime weigh from 280 to 306 pounds.

When coals are used for fuel in a well-constructed perpetual, or draw kiln, about 1 measure of them should suffice for 4 or 5 of limestone.

The most extensive employment of quicklime is in agriculture, on which subject instructive details are given in Loudon's *Encyclopædias of Agriculture and Gardening*.

Quicklime is employed in a multitude of preparations subservient to the arts; for clarifying the juice of the sugar-cane and the beet-root; for purifying coal gas; for rendering the potash and soda of commerce caustic in the soap manufacture, and in the bleaching of linen and cotton; for purifying animal matters before dissolving out their gelatine; for clearing hides of their hair in tanneries; for extracting the pure volatile alkali from muriate or sulphate of ammonia; for rendering confined portions of air very

dry; for stopping the leakage of stone reservoirs, when mixed with clay and thrown into the water; for making a powerful lute with white of egg or serum of blood; for preparing a depilatory pomade with sulphuret of arsenic, &c. Lime water is used in medicine, and quicklime is of general use in chemical researches. Next to agriculture the most extensive application of quicklime is to MORTAR CEMENTS, which see.

LINEN. See FLAX, and TEXTILE FABRICS.

LINEN distinguished from cotton.—Cotton may be distinguished from linen or flax by immersing the former, well washed and dried, for about a minute in strong sulphuric acid. It is then to be withdrawn and washed with water containing a little alkali. The cotton will dissolve as a gummy mass, while the linen will retain its thready texture.

LINSEED (*Graine de lin*, Fr.; *Leinsame*, Germ.); contains in its dry state, 11.265 of oil; 0.146 of wax; 2.488 of a soft resin; 0.550 of a coloring resinous matter; 0.926 of a yellowish substance analogous to tannin; 6.154 of gum; 15.12 of vegetable mucilage; 1.48 of starch; 2.932 of gluten; 2.782 of albumine; 10.884 of saccharine extractive; 44.382 of envelopes, including some vegetable mucilage. It contains also free acetic acid; some acetate, sulphate, and muriate of potash, phosphate and sulphate of lime; phosphate of magnesia; and silica. See OILS, UNCTUOUS.

LINSEED AND FLAXSEED. Imported, for home consumption, in 1850, 608,984 quarters; in 1851, 630,471 qrs.; duty free.

LINSEED OIL, *drying without heat*. When linseed oil is carefully agitated with vinegar of lead (tribasic acetate of lead) and the mixture allowed to clear by settling, a copious white cloudy precipitate forms, containing oxide of lead, whilst the raw oil is converted into a drying oil of a pale straw color, forming an excellent varnish, which when applied in thin layers, dries perfectly in twenty-four hours. It contains from four to five per cent. of oxide of lead in solution. The following proportions appear to be the most advantageous for its preparations.

In a bottle containing 4½ pints of rain water, 18 ounces of neutral acetate of lead are placed, and when the solution is complete, 18 ounces of litharge in a very fine powder are added; the whole is then allowed to stand in a moderately warm place, frequently agitating it to assist the solution of the litharge. This solution may be considered as complete when no more small scales are apparent. The deposit of a shining white color (sexbasic acetate of lead) may be separated by filtration. This conversion of the neutral acetate of lead into vinegar of lead, by means of litharge and water, is effected in about a quarter of an hour, if the mixture be heated to ebullition. When heat is not applied, the process will usually take three or four days. The solution of vinegar of lead, or tribasic acetate of lead, thus formed, is sufficient for the preparation of 22lbs. of drying oil. For this purpose, the solution is diluted with an equal volume of rain water, and to it is gradually added, with constant agitation, 22lbs. of oil, with which 18 ounces of litharge have previously been mixed.

When the points of contact between the lead solution and the oil have been frequently renewed by agitation of the mixture three or four times a day, and the mixture allowed to settle in a warm place, the limpid straw-colored oil rises to the surface, leaving a copious whitish deposit. The watery solution rendered clear by filtration, contains intact all the acetate of lead first employed, and may be used in the next operation, after the addition to it as before of 18 ounces of litharge.

By filtration through paper or cotton the oil may be obtained as limpid as water and by exposure to the light of the sun it may also be bleached.

Should a drying oil be required absolutely free from lead, it may be obtained by the addition of dilute sulphuric acid to the above, when, on being allowed to stand, a deposit of sulphate of lead will take place, and the clear oil may be obtained free from all trace of lead.

Lint for surgery, has been made the subject of a patent by Mr. Thomas Ross, of Coleman Street, which consists in the employment of peculiarly constructed scrapers for braiding the surface of the linen cloth, and producing a pile or nap upon it. The scrapers are worked by a rotary motion.

Instead of rotary scrapers, a reciprocating pendulous movement is sometimes applied to a single scraper. Chisel-formed blades are claimed by the patentee as scrapers for raising the pile, by working with the bevel edges forwards, so as to scrape and not to cut the fabric. He has in the rotary form a ledge or bed concentric with the axis of the scraper, which he also claims; both of which seem to be serviceable. The details and figures may be seen in *Newton's Journal*, xxxvii. 301.

LIQUATION (Eng. and Fr.; *Saigerung*, Germ.); is the process of sweating out, by a regulated heat from an alloy an easily fusible metal from the interstices of a metal difficult of fusion. Lead and antimony are the metals most commonly subjected to liquation; the former for the purpose of carrying off by a superior affinity the silver

present in any complex alloy, a subject discussed under SILVER; the latter will be considered here, as referred to from the article ANTIMONY.

Figs. 871, 872, 873 represent the celebrated antimonial liquation furnaces of Malbosc, in the department of Ardèche, in France. Fig. 871 is a ground plan taken at the level of the draught holes *g g*, fig. 872, and of the dotted line *E F*; fig. 873 is a vertical section through the

dotted line *A B*, of fig. 871; and fig. 873 is a vertical section through the dotted line *C D* of fig. 871. In the three figures, the same letters denote like objects. *a b c* are three grates upon the same level above the floor of the works, $4\frac{1}{2}$ feet long, by $10\frac{1}{2}$ inches broad; between which are two rectangular galleries, *d e*, which pass transversely through the whole furnace, and lie at a level of 12 inches above the ground. They are separated by two walls from the three fire-places. The walls have three openings, *f g h*, alternately placed for the flames to play through. The ends of these galleries are shut in with iron doors *i i*, containing peep holes. In each gallery are two conical cast-iron crucibles *k k*, into which the liquating sulphuret of antimony drops. Their height is from 12 to 14 inches, the width of the mouth is 10 inches, that of the bottom is 6, and the thickness four tenths of an inch. They are coated over with fire-clay, to prevent the sulphuret from acting upon them; and they stand upon cast-iron pedestals with projecting ears, to facilitate their removal from the gallery or platform. Both of these galleries are lined with tiles of fire-clay *l l*, which also serve as supports to the vertical liquation tubes *m m*, made of the same clay. The tiles are somewhat curved towards the middle, for the purpose of receiving the lower ends of these tubes, and have a small hole at *n*, through which the liquid sulphuret flows down into the crucible.

The liquation tubes are conical, the internal diameter at top being 10 inches, at bottom 8; the length fully 40 inches, and the thickness six tenths of an inch. They have at their lower ends notches or slits *o*, fig. 873, from 3 to 5 inches long, which look outwards, to make them accessible from the front and back part of the furnaces through small conical openings *p p*, in the walls. These are closed during the operation with clay stoppers, and are opened only when the gangue, rubbish, and cinders are to be raked out. The liquation tubes pass across the arch of the furnace *q q*, the space of the arch being wider than the tubes; they are shut in at top with fire-covers *r r*. *s s*, the middle part of the arch, immediately under the middle grate, is barrel-shaped, so that both arches are abutted together. The flames, after playing round about the sides of the liquation tubes, pass off through three openings and flues into the chimney *t*, about 13 feet high; *u* being the one opening, and *v* the two others, which are provided with register plates. In front of the furnace is a smoke flue *w*, to carry off the sulphureous vapors exhaled during the clearing out of the rubbish and slag; another, *x*, begins over *y y*, at the top of the tubes; a wall *z*, separates the smoke flue into halves, so that the workmen upon the one side may not be incommoded by the fumes of the other. This wall connects at the same time the front flue *w* with the chimney *t*. *a' a'* and *b' b'* are iron and wooden bearer beams and rods for strengthening the smoke-flue. *c' c'* are arches upon both sides of the furnace, which become narrower from without inwards,

are arches upon both sides of the furnace, which become narrower from without inwards, and are closed with well-fitted plates *d d*. They serve, in particular circumstances, to allow the interior to be inspected, and to see if either of the liquation furnaces be out of order.

Each tube being charged with about 500 lbs. of the antimonial ore, previously warmed upon the roof of the furnace, in a short time the sulphuret of a blue color begins to flow out. Whenever the liquation ceases, the cinders are raked out by the side openings, and the tubes are charged afresh. The luted iron crucibles are suffered to become three-fourths full, are then drawn out from the galleries, left to cool, and emptied. The ingots weigh about 85 pounds. The charging is renewed every three hours, and when the process is in good train, 100 lbs. of sulphuret of antimony are obtained every hour. The average duration of the tubes is 3 weeks, though in some cases it may be 40 days. The product from the ore is from 40 to 50 per cent. The above plan of operation is remarkable for the small consumption of fuel, the economy of labor, and the complete exhaustion of the ore.

LIQUEURS, LIQUORISTE; names given by the French to liquors compounded of alcohol, water, sugar and different aromatic substances; and to the person who compounds them. I shall insert here a few of their most approved recipes.

Infusion of the peels of fruits.—The outer skin pared off with a sharp knife, is to be dropped into a hard glazed jar, containing alcohol of 34° B., diluted with half its bulk of water, and the whole is to be transferred into well-corked carboys. After an infusion of six weeks, with occasional agitation, the aromatized spirit is to be distilled off. In this way are prepared the liquors of cedrat, lemons, oranges, *limettes* (a sort of sweet lemon), *poncires* (the large citron), bergamots, &c.

Infusion of aromatic seeds.—These must be pounded, put into a carboy, along with alcohol diluted as above, infused with agitation for six weeks, and then distilled.

Infusion of aromatic woods are made in the same way.

The liquorist should not bring his infusions and tinctures into the market till six months after their distillation.

Liqueurs have different titles, according to their mode of fabrication.

Thus *waters*, are liquors apparently devoid of viscosity; *creams* and *oils* possess it in a high degree.

Water of cedrat, is made by dissolving six pounds of sugar in seven quarts of water, adding two quarts of spirit of cedrat, and one of spirit of citron. Boil the whole for a minute, and filter hot through a proper bag. Set it for a considerable time aside in a corked carboy, before it be bottled.

Oil or cream of cedrat.—Take eight quarts of river water, two of spirits of cedrat, one of spirit of citron, and as much rich syrup as is necessary to give the mixture an oily consistence. Stir it well and set it aside in carboys. Should it be at all clouded, it must be filtered till it be perfectly pellucid.

Balm of Molucca, is made by infusing for ten days, in a carboy capable of holding fully four gallons, 10 pounds of spirits of 18° B., 4 pounds of white sugar, 4 pounds of river water, 4 drachms of pounded cloves, and 48 grains of pounded mace. The mixture is to be shaken 3 or 4 times daily, colored with caramel (burnt sugar), filtered at the end of ten days, and set aside in bottles.

Tears of the widow of Malabar, are compounded with the preceding quantity of spirits, sugar, and water, adding four drachms of ground cinnamon, 48 grains of cloves, and a like quantity of mace, both in powder. It may be slightly colored with caramel.

The delight of the Mandarins.—Take spirit, sugar and water, as above, adding 4 drachms of *anisum Chinæ* (*Gingi*), as much *ambretta* (seeds of the *hibiscus abelmoschus*, Lin.) all in powder; 2 drachms of safflower.

The sighs of love.—Take spirits, water, and sugar, as above. Perfume with essence (otto) of roses; give a very pale pink hue with tincture of cochineal, filter and bottle up.

Crème de macarons.—Add to the spirit, sugar, and water as above, half a pound of bitter almonds, blanched and pounded; cloves, cinnamon, and mace in powder, of each 48 grains. A violet tint is given by the tinctures of turnsole and cochineal.

Curaçoa.—Put into a large bottle nearly full of alcohol of *trente-six* (34° Baumé), the peels of six smooth Portugal oranges, (Seville?) and let them infuse for 15 days; then put into a carboy 10 pounds of spirits of 18° B., 4 pounds of white sugar, and 4 pounds of river water. When the sugar is dissolved, add a sufficient quantity of the orange *zestes* to give flavor, then spice the whole with 48 grains of cinnamon, and as much mace, both in powder. Lastly introduce an ounce of ground Brazil wood, and infuse during 10 days, agitating 3 or four times daily. A pretty deep hue ought to be given with caramel.

Swiss extract of wormwood, is compounded as follows:—

Tops of the *absinthium majus* 4 pounds;

Ditto, *absinthium minus* 2 pounds;

Roots of angelica, Calamus aromaticus, Seeds of the <i>anisum China</i> , Leaves of the dittany of Crete, Alcohol of 20° B., four gallons Imp.	} of each a few grains at pleasure;
--	-------------------------------------

Macerate these substances during eight days, then distil by a gentle fire; draw off two gallons of spirits, and add to it 2 drachms of essential oil of anise-seed. The two gallons left in the still serve for preparing the *vulnerary spirituous water*.

Of coloring the *liqueurs*.

Yellow is given with the yellow coloring matter of sunflower (*carthamus*), which is readily extracted by water.

Faen is given by *caramel*, made by heating ground white sugar in an iron spoon over a charcoal fire, till it assumes the desired tint, and then pouring it into a little cold water.

Red is given by cochineal alone, or with a little alum.

Violet is given by good litmus (turnsole).

Blue and green.—Sulphate of indigo gives the first. After saturating it nearly with chalk, alcohol being digested upon it, becomes blue. This tincture mixed with that of *carthamus* forms a good green.

LIQUIDAMBER, is obtained from the *liquidambar styraciflua*, a tree which grows in Mexico, Louisiana and Virginia. Some specimens are thin, like oil, and others are thickish, like turpentine. It is transparent, amber colored, has an agreeable and powerful smell, and an aromatic taste, which feels pungent in the throat. Boiling alcohol dissolves it almost entirely. It contains a good deal of benzoic acid, some of which effloresces whenever the liquidamber hardens with keeping.

LITHARGE (Eng. and Fr.; *Glatte*, Germ.); is the fused yellow protoxide of lead, which on cooling passes into a mass consisting of small six-sided plates, of a reddish yellow color, and semi-transparent. It generally contains more or less red lead, whence the variations of its color; and carbonic acid, especially when it has been exposed to the air for some time. See **LEAD** and **SILVER**, for its mode of preparation.

LITHIA, is a simple earthy or alkaline substance, discovered not many years ago in the minerals called petalite and tephane. It is white, very caustic, reddens litmus, and red cabbage, and saturates acids with great facility. When exposed to the air it attracts humidity and carbonic acid. It is more soluble in water than baryta; and has such a strong affinity for it as to be obtained only in the state of a hydrate. It forms neutral salts with all the acids. It is most remarkable for its power of acting upon or corroding platinum.

LITHIUM, is the metallic basis of lithia; the latter substance consists of 100 of metal, and 123 of oxygen.

LITHOGRAPHIC PRESS. The lithographic press in common use has long been regarded as a very inadequate machine. The amount of manual power required to work it, and the slow speed at which, under the most favorable circumstances, copies can be produced, disables lithography in its competition with letter-press. A career of brilliant success has attended the efforts of scientific men towards speed and perfection in this latter branch of the art; and the present printing machines surpass the hand-press somewhat in the same ratio, as does our express speed the jog trot of our forefathers. The engravings annexed will serve to illustrate Messrs. Napier & Sons'

improvements upon the lithographic press. The machine is arranged to be driven by steam power; has belts, "crossed" and "open," supposed to be in connection with the engine, and to run upon the pulleys A, B, C. The crank pulley, B, is fixed on the screw

spindle *n*, and the other two work loose, or "dead," on the same spindle; these bands with their striking forks, *a*, are arranged so as to be brought alternately upon the fixed pulley, *n*, and thus a reversing motion is given to the screw. The nut in which the screw works is fixed to a crosspiece *r*, which braces the side frames *r*, together at bottom, while the bar *a*, performs the same office at top; the scraper box, *n*, is sustained between these frames at bearings *i*, and is so fitted as to work freely. To support the frames and scraper box independent of the screw, and maintain them in position, allowing freedom of action, the rollers *j*, *j*, are provided, which run in the planed recesses, *k*, along the top of the main standards *L*.

The machine is shown with its tympan down, ready for starting; this is effected by pressing lightly upon the lever, *b*, which raises a catch, and allows the weight *m*, to descend in the direction of its present inclination, and act upon the connections with the striking forks, so as to bring one of the bands upon the fast pulley *n*, and make the scraper and its frames move forward. The return is caused by the frame *r*, coming in contact with a stop *c*, which yielding, acts upon the striking forks by its bar *d*, upon which it may be adjusted to give the travel required. On the return being accomplished the machine stops itself by a striking action against stop *e*, the catch *b*, falling in to prevent the weight descending to its full throw, and thus retaining the two bands upon the two dead pulleys, *A* and *C*, while the machine is prepared for another impression.

The action of the scraper is peculiar and novel; it is balanced, so that its tendency is to remain slightly raised, but in its forward movement, and at the point desired, it is made to descend by a stop fixed upon the top of the main standard, *L*, into a position vertical or nearly so, in which position it is retained by its own onward progress against strong abutments projecting from the frames, *r*; on the return it resumes its raised position and passes back without impediment. The scraper may be adjusted to give the pressure desired, or the table on which the stone is placed regulated by screws.

The advantages embodied in this machine will be at once recognized by those interested. The pulling down of the scraper, and the labor and inconvenience attendant upon that operation, are entirely superseded by the simple and effectual valve-like movement just explained, which forms the groundwork of this combination, although it will alike apply to the press-work by hand, and is the most striking novelty in the machine.

LITHOGRAPHY. Though this subject belongs rather to the arts of taste and design than to productive manufactures, its chemical principles fall within the province of this Dictionary.

The term *lithography* is derived from *λίθος* a stone, and *γραφη*, writing, and designates the art of throwing off impressions upon paper, of figures and writing previously traced upon stone. The processes of this art are founded:—

1. Upon the adhesion to a smoothly-polished limestone, of an encaustic fat which forms the lines or traces.
2. Upon the power acquired by the parts penetrated by this encaustic, of attracting to themselves, and becoming covered with a printer's ink, having linseed oil for its basis.
3. Upon the interposition of a film of water, which prevents the adhesion of the ink in all the parts of the surface of the stone not impregnated with the encaustic.
4. Lastly, upon a pressure applied by the stone, such as to transfer to paper the greater part of the ink which covers the greasy tracings of the encaustic.

The lithographic stones of the best quality are still procured from the quarry of Solenhofen, a village at no great distance from Munich, where this mode of printing had its birth. They resemble in their aspect the yellowish white lias of Bath, but their geological place is much higher than the lias. Abundant quarries of these fine-grained

limestones occur in the county of Pappenheim, along the banks of the Danube, presenting slabs of every required degree of thickness, parted by regular seams, and ready for removal with very little violence. The good quality of a lithographic stone is generally denoted by the following characters: its hue is of a yellowish grey, and uniform throughout; it is free from veins, fibres, and spots; a steel point makes an impression on it with difficulty; and the splinters broken off from it by the hammer display a conchoidal fracture.

The Munich stones are retailed on the spot in slabs or layers of equal thickness; they are quarried with the aid of a saw, so as to sacrifice as little as possible of the irregular edges of the rectangular tables or plates. One of the broad faces is then dressed, and coarsely smoothed. The thickness of these stones is nearly proportional to their other dimensions; and varies from 1½ inches to 3 inches.

In each lithographic establishment, the stones receive their finishing, dressing and polishing; which are performed like the grinding and polishing of mirror plate. The work is done by hand, by rubbing circularly a moveable slab over another cemented in a horizontal position, with fine sifted sand and water interposed between the two. The style of work that the stone is intended to produce determines the kind of polish that it should get. For crayon drawing the stone should be merely grained more or less fine according to the fancy of the draughtsman. The higher the finish of the surface, the softer are the drawings; but the printing process becomes sooner *pasty*, and a smaller number of impressions can be taken. *Works in ink* require the stone to be more softened down, and finally polished with pumice and a little water. The stones thus prepared are packed for use with white paper interposed between their faces.

Lithographic crayons.—Fine lithographic prints cannot be obtained unless the crayons possess every requisite quality. The ingredients composing them ought to be of such a nature as to adhere strongly to the stone, both after the drawing has undergone the preparation of the acid, and during the press-work. They should be hard enough to admit of a fine point, and trace delicate lines without risk of breaking. The following composition has been successfully employed for crayons by MM. Bernard and Delarue, at Paris.

Pure wax, (first quality)	-	-	-	-	-	4
Dry white tallow soap	-	-	-	-	-	2
White tallow	-	-	-	-	-	2
Gum lac	-	-	-	-	-	2
Lamp-black, enough to give a dark tint	-	-	-	-	-	1
Occasionally copal varnish	-	-	-	-	-	1

The wax is to be melted over a gentle fire, and the lac broken into bits is then to be added by degrees, stirring all the while with a spatula; the soap is next introduced in fineshavings; and when the mixture of these substances is very intimately accomplished, the copal-varnish, incorporated with the lamp-black, is poured in. The heat and agitation are continued till the paste has acquired a suitable consistence; which may be recognized by taking out a little of it, letting it cool on a plate, and trying its quality with a penknife. This composition, on being cut, should afford brittle slices. The boiling may be quickened by setting the rising vapors on fire, which increases the temperature, and renders the exhalations less offensive. When ready, it is to be poured into a brass mould, made of two semi-cylinders joined together by clasps or rings, forming between them a cylindric tube of the crayon size. The mould should be previously smeathed with a greasy cloth.

M. Lasteyrie prescribes a more simple composition, said to be equally fit for the lithographer's use:—

Dried white tallow soap	-	-	-	-	-	6 parts.
White wax	-	-	-	-	-	6 —
Lamp-black	-	-	-	-	-	1 —

The soap and tallow are to be put into a small goblet and covered up. When the whole is thoroughly fused by heat, and no clots remain, the black is gradually sprinkled in with careful stirring.

Lithographic ink is prepared nearly on the same principle:—

Wax	-	-	-	-	-	16 parts.
Tallow	-	-	-	-	-	6 —
Hard tallow soap	-	-	-	-	-	6 —
Shell-lac	-	-	-	-	-	12 —
Mastic in tears	-	-	-	-	-	8 —
Venice turpentine	-	-	-	-	-	1 —
Lamp-black	-	-	-	-	-	4 —

The mastic and lac, previously ground together, are to be heated with care in the turpentine; the wax and tallow are to be added after they are taken off the fire, and when their solution is effected, the soap shavings are to be thrown in. Lastly the lamp black is to be well intermixed. Whenever the union is accomplished by heat, the operation is finished; the liquor is left to cool a little, then poured out on tables, and, when cold, cut into square rods.

Lithographic ink of good quality ought to be susceptible of forming an emulsion so attenuated, that it may appear to be dissolved when rubbed upon a hard body in distilled or river water. It should be flowing in the pen, not spreading on the stone; capable of forming delicate traces, and very black to show its delineations. The most essential quality of the ink is to sink well into the stone, so as to re-produce the most delicate outlines of the drawing, and to afford a great many impressions. It must therefore be able to resist the acid with which the stone is moistened in the preparation, without letting any of its greasy matter escape.

M. de Lasteyrie states that after having tried a great many combinations, he gives the preference to the following:—

Tallow soap, dried - - - - -	30 parts
Mastic, in tears - - - - -	30 —
White soda of commerce - - - - -	30 —
Shellac - - - - -	150 —
Lamp-black - - - - -	12 —

The soap is first put into the goblet and melted over the fire, to which the lac being added fuses immediately; the soda is then introduced, and next the mastic, stirring all the while with a spatula. A brisk fire is applied till all these materials be melted completely, when the whole is poured out into the mould.

The inks now prescribed may be employed equally with the pen and the hair pencil, for writings, black-lead drawings, *aqua tinta*, mixed drawings, those which represent engravings on wood (wood cuts), &c. When the ink is to be used it is to be rubbed down with water, in the manner of China ink, till the shade be of the requisite depth. The temperature of the place ought to be from 84° to 90° Fahr., or the saucer in which the ink-stick is rubbed should be set in a heated plate. No more ink should be dissolved than is to be used at the time, for it rarely keeps in the liquid state for 24 hours; and it should be covered or corked up.

Autographic paper.—Autography, or the operation by which a writing or a drawing is transferred from paper to stone, presents not merely a means of abridging labor, but also that of reverting the writings or drawings into the direction in which they were traced, whilst, if executed directly upon the stone, the impression given by it is inverted. Hence, a writing upon stone must be inverted from right to left to obtain direct impressions. But the art of writing thus is tedious and difficult to acquire, while, by means of the autographic paper and the transfer, proofs are obtained in the same direction with the writing and drawing.

Autographic ink.—It must be fatter and softer than that applied directly to the stone, so that though dry upon the paper, it may still preserve sufficient viscosity to stick to the stone by mere pressure.

To compose this ink, we take—

White soap - - - - -	100 parts
White wax of the best quality - - - - -	100 —
Mutton suet - - - - -	30 —
Shellac - - - - -	50 —
Mastic - - - - -	50 —
Lamp-black - - - - -	30 or 35 —

These materials are to be melted as above described for the lithographic ink.

Lithographic ink and paper.—The following recipes have been much commended:—

Virgin or white wax - - - - -	8 parts
White soap - - - - -	2 —
Shellac - - - - -	2 —
Lamp-black - - - - -	3 table-spoonsful.

Preparation.—The wax and soap are to be melted together, and before they become so hot as to take fire, the lamp-black is to be well stirred in with a spatula, and then the mixture is to be allowed to burn for 30 seconds; the flame being extinguished, the lac is to be added by degrees, carefully stirring all the time; the vessel is to be put upon the fire once more in order to complete the combination, and till the materials are either kindled or nearly so. After the flame is extinguished, the ink must be suffered to cool a little, and then put into the moulds.

With the ink crayons thus made, lines may be drawn as fine as with the point of the graver, and as full as can be desired, without risk of its spreading in the carriage. Its traces will remain unchanged on paper for years before being transferred.

Some may think it strange that there is no suet in the above composition, but it has been found that ink containing it is only good when used soon after it is made, and when immediately transferred to the stone, while traces drawn on paper with the suet ink become defective after 4 or 5 days.

Lithographic paper.—Lay on the paper, 3 successive coats of sheep-feet jelly,

1 layer of white starch,

1 layer of gamboge.

The first layer is applied with a sponge dipped in the solution of the hot jelly, very equally over the whole surface, but thin; and if the leaf be stretched upon a cord, the gelatine will be more uniform. The next two coats are to be laid on, until each is dry. The layer of starch is then to be applied with a sponge, and it will also be very thin and equal. The coat of gamboge is lastly to be applied in the same way. When the paper is dry, it must be smoothed by passing it through the lithographic press; and the more polished it is, the better does it take on the ink in fine lines.

Transfer.—When the paper is moistened, the transfer of the ink from the gamboge is perfect and infallible. The starch separates from the gelatine, and if, after taking the paper off the stone, we place it on a white slab of stone, and pour hot water over it, it will resume its primitive state.

The coat of gamboge ought to be laid on the same day it is dissolved, as by keeping it becomes of an oily nature; in this state it does not obstruct the transfer, but it gives a gloss to the paper which renders the drawing or tracing more difficult, especially to persons little habituated to lithography.

The starch paste can be employed only when cold, the day after it is made, and after having the skin removed from its surface.

A leaf of such lithographic paper may be made in two minutes.

In transferring a writing, an ink drawing, or a lithographic crayon, even the impression of a copper-plate, to the stone, it is necessary, 1. that the impressions be made upon a thin and slender body like common paper; 2. that they may be detached and fixed totally on the stone by means of pressure; but as the ink of a drawing sinks to a certain depth in paper, and adheres pretty strongly, it would be difficult to detach all its parts, were there not previously put between the paper and the traces, a body capable of being separated from the paper, and of losing its adhesion to it by means of the water with which it is damped. In order to produce this effect, the paper gets a certain preparation, which consists in coating it over with a kind of paste ready to receive every delineation without suffering it to penetrate into the paper. There are different modes of communicating this property to paper. Besides the above, the following may be tried. Take an unsized paper, rather strong, and cover it with a varnish composed of:—

Starch	-	-	-	-	-	120 parts
Gum arabic	-	-	-	-	-	40 —
Alum	-	-	-	-	-	20 —

A paste of moderate consistence must be made with the starch and some water, with the aid of heat, into which the gum and alum are to be thrown, each previously dissolved in separate vessels. When the whole is well mixed, it is to be applied, still hot, on the leaves of paper, with a flat smooth brush. A tint of yellow color may be given to the varnish, with a decoction of the berries of Avignon, commonly called French berries by our dyers. The paper is to be dried, and smoothed by passing under the scraper of the lithographic press.

Steel pens are employed for writing and drawing with ink on the lithographic stones.

LITMUS (*Tournesol*, Fr.; *Lackmus*, Germ.) is prepared in Holland from the species of lichen called *Lecanora tartarea*, *Roccella tartarea*, by a process which has been kept secret, but which is undoubtedly analogous to that for making archil and eudbear. The ground lichens are first treated with urine containing a little potash, and allowed to ferment, whereby they produce a purple-red; the colored liquor, treated with quicklime and some more urine, is set again to ferment during two or three weeks, then it is mixed with chalk or gypsum into a paste, which is formed into small cubical pieces, and dried in the shade. Litmus has a violet-blue color, is easy to pulverize, is partially soluble in water and dilute alcohol, leaving a residuum consisting of carbonate of lime, of clay, silica, gypsum, and oxyde of iron combined with the dye. The color of litmus is not altered by alkalis, but is reddened by acids; and is therefore used in chemistry as a delicate test of acidity, either in the state of solution or of unsized paper stained with it. It is employed to dye marble blue.

* *LIXIVIATION* (*Lessivage*, Fr.; *Auslagen*, Germ.) signifies the abstraction by water

of the soluble alkaline or saline matters present in any earthy admixture; as from that of quicklime and potashes to make potash lye, from that of effloresced alum schist to make aluminous liquors, &c.

LOADSTONE, MAGNETIC IRON-STONE (*Fer oxydulé*, Fr.; *Magneteisenstein*, Germ.); an iron ore consisting of the protoxide and peroxide of iron in a state of combination.

LOAM (*Terre limonneuse*, Fr.; *Lehm*, Germ.); a native clay mixed with quartz sand and iron ochre, and occasionally with some carbonate of lime.

LOCK (BANK SAFE). The peculiarity of this lock consists in an extension of the key after it is inserted in the lock, and a secret connection between the interior of the key and two of the players. The two inclined planes on the under side of the wards open or shut the extension of the key as it passes over them: the part of the key thus extended operates on two players placed beyond the reach of picklocks, while at the same time the main part of the key works other two players, which are again operated on by the secret apparatus in the interior of the key. This secret apparatus can be removed at pleasure, and the proper key then becomes unfit to work the lock, and skeleton keys, however well fitted to pass the wards, will not operate on the players.

LODE, is the name given by the Cornish miners to a vein, whether it be filled with metallic or earthy matter.

LOGWOOD (*Bois de Campêche*, *Bois bleu*, Fr.; *Blauholz*, Germ.; is the wood of the *Hæmatoxylon Campechianum*, a native tree of central America, grown in Jamaica since 1715. It was first introduced into England in the reign of Elizabeth, but as it afforded to the unskilful dyers of her time a fugitive color, it was not only prohibited from being used, under severe penalties, but was ordered to be burned wherever found, by a law passed in the 23d year of her reign. The same prejudice existed, and the same law was enacted against indigo. At length, after a century of absurd prohibition, these two most valuable tinctorial matters, by which all our hats, and the greater part of our woollen cloths are dyed, were allowed to be used.

Old wood, with black bark and with little of the white alburnum, is preferred. Logwood is denser than water, very hard, of a fine compact grain, and almost indestructible by the atmospheric elements; it has a sweet and astringent taste, and a peculiar not inoffensive smell.

For its chemical composition, see **HEMATIN**.

When chipped logwood is for some time exposed to the air, it loses a portion of its dyeing power. Its decoction absorbs the oxygen of the atmosphere, and then acquires the property of precipitating with gelatine, which it had not before. The dry extract of logwood, made from an old decoction, affords only a fugitive color.

For its applications in dyeing, see **BLACK DYE**; **BROWN DYE**; **CALICO PRINTING**; **DYEING**; **HAT DYEING**, &c.

The imports of logwood were in 1850, 34,690 tons; in 1851, 21,240 tons; of which 3,721 tons and 3,010 tons respectively were re-exported.

LOOM (*Métier à tisser*, Fr.; *Weberstuhl*, Germ.); is the ancient and well-known machine for weaving cloth by the decussation of a series of parallel threads, which run lengthwise, called the warp or chain, with other threads thrown transversely with the shuttle, called the woof or weft. See **JACQUARD LOOM WEAVING**.

LUBRICATION. The following simple and efficacious plan of lubricating the joints and bearings of machinery by capillary attraction, has been kindly communicated to me, by its ingenious inventor, Edward Woolsey, Esq.:

Fig. 876. represents a tin cup, which has a small tin tube *A*, which passes through the bottom, as shown by the dotted lines. It may have a tin cover to keep out the dust.

Fig. 877. is a plan of the same.

Fig. 878. is a section of the same. Oil is poured into the cup, the one end of a worsted or cotton thread is dipped into the oil, and the other end passed through the tube. The capillary attraction causes the oil to ascend and pass over the orifice of the tube, whence it gradually descends, and drops slower or quicker, according to the length of the thread or its thickness, until every particle of oil is drawn over by this capillary syphon. The tube is intended to be put into the bearings of shafts, &c., and is made of any size that may be wished. If oil, or other liquids, is desired to be dropped upon a grindstone or other surface, this cup can have a handle to it, or be hung from the ceiling.

Fig. 879. It is frequently required to stop the capillary action when the machinery is not going; and this has been effected by means of a tightening screw, which passes through a screw boss in the cover of the cup, and presses against the internal orifice of the tube preventing the oil from passing.

Fig. 880. As I find when these screw cups (*fig. 879*), are used upon beams of engines and moving bearings, that the screw is apt to be tightened by the motion; and also as I think the action of the screw is uncertain, from the workmen neglecting to screw it down sufficiently, it answers best to take out the capillary thread when the lubrication

is not required and to effect this easily, I have a tin top to the cup, with a round pipe soldered to it: this pipe has a slit in it, like a pencil-case, and allows a bolt *a*, to slide easily in it. In *fig.* 881, the bolt is down; in *fig.* 882, the bolt, which is a piece of brass wire, is drawn up, and there is no capillary action between the thread and the oil. In *fig.* 882, it will be observed, that the bolt is kept in its place by its head *c*, resting in a lateral slit in the pipe, and it cannot be drawn out on account of the pin *e*. One end of the thread is fastened to the eye hole at the bottom of the bolt, and the other end is tied to a small wire which crosses the lower orifice of the tube at *n*, and which is shown in plan *fig.* 883.

By this simple contrivance the capillary action can be stopped or renewed in a second, without removing the top of the lubricator.

The saving by this plan, instead of pouring oil into the bearings, is 2 gallons out of 3, while the bearings are better oiled.

"I send you the drawings of the lubricators, with a detailed explanation. I have omitted to state, that the saving in labor is considerable where there are many joints to keep oiled three or four times a day; and that the workman does not with this apparatus, run the risk of being caught by the machinery. Perhaps your friends may be at a loss how to tie on the cotton or worsted thread. I pass a long thread through the eye-hole *e* of the bolt, and then draw the two ends through the tube by a fine wire with a hook to it, one end on one side of the cross wire *n*, and the other end on the other side. I then put the cover on, and the bolt in the position shown in *fig.* 651; when by drawing the two ends of the thread, and tying them across the wire *n*, you have the exact length required. When you wish to see the quantity of oil remaining in the lubricator, the bolt must be dropped as in *fig.* 650, and you can then lift the cover a little way off, without breaking the thread, and replenish with oil. The cost of *fig.* 650, in tin plate, is 9d. The figures in the wood cuts are one third of the full size.

"Believe me to be yours sincerely,

"E. J. WOOLSEY."

LUPULINE, is a substance of a gummy appearance, so named by M. Cussola, because it was obtained from Lupines.

LUPULINE, from *Humulus Lupulus*; is the peculiar bitter aromatic principle of the hop. See BEER.

LUTE (from *lutum*, clay; *Lut*, Fr.; *Kitte*, *Beschläge*, Germ.), is a pasty or loamy matter employed to close the joints of chemical apparatus, or to coat their surfaces, and protect them from the direct action of flame. Lutes differ according to the nature of the vapors which they are destined to confine, and the degree of heat which they are to be exposed to.

1. *Lute of linseed meal*, made into a soft plastic dough with water, and immediately applied pretty thick to junctions of glass or stone ware, makes them perfectly tight, hardens speedily, resists acid and ammoniacal vapors, as also a moderate degree of heat. It becomes stronger when the meal is kneaded with milk, lime-water, or solution of glue.

2. *Lute of thick gum-water*, kneaded with clay, and iron filings, serves well for permanent junctions, as it becomes extremely solid.

3. By softening in water a piece of thick brown paper, kneading it first with rye-flour paste, and then with some potter's clay, till it acquire the proper consistence, a lute is formed which does not readily crack or scale off.

4. *Lute*, consisting of a strong solution of glue kneaded into a dough with new slaked lime, is a powerful cement, and with the addition of white of egg forms the *lute d'ane*;—a composition adapted to mend broken vessels of porcelain and stone-ware.

5. Skim-milk cheese, boiled for some time in water, and then triturated into paste with fresh-slaked lime, forms also a good lute.

6. Calcined gypsum, diffused through milk, solution of glue or starch, is a valuable lute in many cases.

7. A lute made with linseed, melted caoutchouc, and pipe-clay, incorporated into a smooth dough, may be kept long soft, when covered in a cellar, and serves admirably to confine acid vapors. As it does not harden, it may therefore be applied and taken off as often as we please.

8. Caoutchouc itself, after being melted in a spoon, may be advantageously used for securing joints against chlorine and acid vapors, in emergencies when nothing else would be effectual. It bears the heat at which sulphuric acid boils.

9. The best lute for joining crucibles inverted in each other, is a dough made with a mixture of fresh fire-clay and ground fire-bricks, worked with water. That cement, if made with solution of borax, answers still better, upon some occasions, as it becomes a compact vitreous mass in the fire. See **CEMENTS**.

LUTE for confining acids. 1 part of caoutchouc dissolved in two parts of hot linseed-oil, and worked up with pipe clay (3 parts) into a plastic mass. Linseed meal and water forms the best lute for fluo-silicic acid.

LUTEOLINE, is a yellow coloring matter discovered by Chevreul in weld. When sublimed, it crystallizes in needles.

LYCOPodium CLAVATUM. The seeds of the lycopodium ripen in September. They are employed, on account of their great combustibility, in theatres, to imitate the sudden flash of lightning, by throwing a quantity of them from a powder puff, or bellows, across the flame of a candle.

LYDIAN STONE, is flint-slate.

M.

MACARONI, is a dough of fine wheat flour, made into a tubular or pipe form, of the thickness of goose-quills, which was first prepared in Italy, and introduced into commerce under the name of Italian or Genoese paste. The wheat for this purpose must be ground into a coarse flour, called *grauu* or *semoule*, by the French, by means of a pair of light mill-stones, placed at a somewhat greater distance than usual. This *semoule* is the substance employed for making the dough. For the mode of manufacturing it into pipes, see **VERMICELLI**.

MACE, is a somewhat thick, tough, unctuous membrane, reticulated or chapt, of a yellowish-brown or orange color. It forms the envelope of the shell of the fruit of the *myristica moschata*, which contains the nutmeg. It is dried in the sun, after being dipped in brine; sometimes it is sprinkled over with a little brine, before packing, to prevent the risk of moulding. Mace has a more agreeable flavor than nutmeg; with a warm and pungent taste. It contains two kinds of oil; the one of which is unctuous, bland, and of the consistence of butter; the other is volatile, aromatic, and thinner. The membrane is used as a condiment in cookery, and the aromatic oil in medicine.

The quantity imported in 1850 was 77,337 lbs.; in 1851, 74,863 lbs.; entered for consumption, 1850, 21,997 lbs.; 1851, 21,695 lbs.; duty received, respectively, 2,887*l.* and 2,847*l.*

MACERATION (Eng. and Fr. *Einweichen*, Germ.), is a preparatory steep to

which certain vegetable and animal substances are submitted, with the view of distending their fibres or pores, and causing them to be penetrated by such menstrua as are best adapted to extract their soluble parts. Water, alone, or mixed with acids, alkalis, or salts; alcohol and ether, are the liquids usually employed for that purpose.

MACHINES (Self-acting.) *The application of self-acting Machines to the Construction of Machinery.* It is nearly half a century since I first became acquainted with the engineering profession, and at that time the greater part of our mechanical operations were done by hand. On my first entrance into Manchester there were no self-acting tools, and the whole stock of an engineering or machine establishment might be summed up in a few ill-constructed lathes, a few drills, and boring machines of rude construction. Now compare any of the present works with what they were in those days, and you will find a revolution of so extraordinary a character, as to appear to those unacquainted with the subject as scarcely entitled to credit. The change thus effected, and the improvements introduced into our constructive machinery, are of the highest importance; and it gives me pleasure to add that they chiefly belong to Manchester, are of Manchester growth, and from Manchester they have had their origin. It may be interesting to know something of the art of tool-making, and of the discoveries and progress of machines which have contributed so largely to multiply the manufactures, as well as the construction of other machines employed in practical mechanics. In Manchester the art of calico-printing was in its infancy forty years ago; the flat press, and one or at the most two colored machines, were all that were then in use; the number of those machines is now greatly multiplied, and some of them are capable of printing eight colors at once; and the arts of bleaching, dyeing, and finishing, have undergone equal extension and improvement. In the manufacture of steam-engines there were only three or four establishments that could make them, and those were Bolton and Watt, of Soho; Fenton, Murray and Wood, of Leeds, and Messrs. Sherratts of this town. The engines of that day ranged from 3 to 50 or at the most 70 horses' power; now they are made as high as 500, or in pairs from 1,000 to 1,200 horse. An order for a single engine at that time was considered a great work, and frequently took ten or twelve months to execute; now they are made by dozens, and that with a degree of despatch as to render it no uncommon occurrence to see five or six engines of considerable power leave a single establishment in a month. In machine making the same powers of production are apparent. In this department we find the same activity, the same certainty of action, and greatly increased production in the manufacture of the smaller machines, than can possibly be attained in the larger and heavier description of work. The self-acting, turning, planing, grooving, and slotting machines have afforded so much accuracy and facility for construction, as to enable the mechanical practitioner to turn, bore, and shape with a degree of certainty almost amounting to mathematical precision. The mechanical operations of the present day could not have been accomplished at any cost thirty years ago, and what was considered impossible at that time, is now performed with a degree of intelligence and exactitude that never fail to accomplish the end in view, and reduce the most obdurate mass to the required consistency, in all those forms so strikingly exemplified in the workshops of engineers and machinists. To the intelligent and observant stranger who visits these establishments, the first thing that strikes his attention is, the mechanism of the self-acting tools, the ease with which they cut the hardest iron and steel, and the mathematical accuracy with which all the parts of a machine are brought into shape. When these implements are carefully examined, it ceases to be a wonder that our steam-engines and machines are so beautifully and correctly executed. We perceive the most curious and ingenious contrivances adapted to every purpose, and machinery which only requires the attendance of a boy to supply the material and apply the power, which is always at hand. In conclusion, I would observe that it is an honor to this country, that we stand at the head of the engineering and mechanical profession. It is an art—I would call it a science—which has occupied the attention of the greatest men from the days of Galileo and Newton down to those of Watt and Smeaton, and it now receives attentive consideration from some of the ablest and most distinguished men of the present time. And of these I may instance Poncelet, Morin, Humboldt, Brewster, Babbage, Dr. Robinson (of Armagh), Willis and many others, to show the interest that is taken by these great men in the advancement of mechanical science. A great deal has been done, but a great deal more may yet be accomplished, if by suitable instruction we carefully store the minds of our foremen and operatives with useful knowledge, and afford them those opportunities essential to its acquisition. We must try to unite theory with practice, and bring the philosopher into close contact with the practical mechanic. We must try to remove prejudices, and to encourage a sounder system of management in the manufactures, design, and projects of the useful arts. When this is accomplished, we shall no longer witness abortions in construction, but a carefully well-digested system of operations, founded on the unerring laws of physical truth.—*W. Fairbairn, Esq.*

MACHINERY FOR CASK-MAKING. A novel method of constructing casks, barrels, and all vessels connected with cooperage, may be seen in operation at the Patent Cooperage Works in Wenlock Road, City Road. By the employment of the steam-engine, the circular saw, and a recently-invented jointing and backing machine, a cask of the largest dimensions can be completely formed and made ready for use in the short space of five minutes, from the raw material, viz., a piece of oak. The staves of the cask are first cut with straight sides, the circular saw being placed at a right angle with the oak plank. The stave is then placed horizontally, and bent into a curve by a powerful machine, and brought into contact with a circular saw on each side of it, placed at an angle. This process gives the proper shape to the stave, the sides being gradually tapered at the ends, and made to bulge in the middle. The jointing and backing machine, the new invention, is also used for this purpose, and is more rapid in its execution than the angular saws; it in fact works with the most marvellous rapidity and precision. The staves and one end of the cask are then placed in a machine formed of iron rods, called a trussing machine; each rod acts upon a separate stave, and the whole of the staves being equally compressed into a circle, the hoops are placed around them, and the cask is complete. The neatness and finish of the work are equal to what a good cabinet-maker can produce, every part being true and accurate. The calculation is, that 15 workmen, with the use of this machine, can make 150 casks a day; whereas the same number of persons, using only manual labor, could scarcely produce a seventh part of that number. The importance of the invention and the application of steam power to it, may be imagined from the fact that the great brewing firms of the metropolis alone expend many thousand pounds annually in cooperage, that the expenditure of the Navy is still greater, and that the demand of the vintages of the continent is so great that a great deal of wine is lost from the difficulty of furnishing vessels to hold it. The process of this invention will repay the time of a visit to the works.

MACLE, is the name of certain diagonal black spots in minerals, like the ace of diamonds in cards, supposed to proceed from some disturbance of the particles in the act of crystallization.

MADDER (*Garance*, Fr.; *Faberröthe*, Germ.), a substance very extensively used in dyeing, is the root of the *Rubia tinctorum*, a plant of which two species are distinguished by Linnæus.

The best roots are those which have the size of a writing quill, or, at most, of the little finger. They are semi-transparent, and reddish; have a strong odor, and a smooth bark. They should be of two or three years' growth.

The madder, taken from the ground and picked, must be dried in order to be ground and preserved. In warm climates it is dried in the open air; but elsewhere stoves must be employed.

The stringy filaments and epidermis are to be removed, called *mulle*; as also the pith, so as to leave nothing but the ligneous fibres.

The preparation of madders is carried on in the department of the Rhone, in the following manner.

The roots are dried in a stove heated by means of a furnace, from which the air is allowed to issue only at intervals, at the moment when it is judged to be saturated with moisture. The furnace-flue occupies a great portion of the floor; above are three close gratings, on which the roots are distributed in layers of about two decimetres (nearly 8 inches). At the end of 24 hours, those which are on the first grated floor directly above the stove are dry, when they are taken away and replaced by those of the superior floors. This operation is repeated whenever the roots over the stove are dry. The dry roots are thrashed with a flail, passed through fanners similar to those employed for corn, and then shaken upon a very coarse sieve. What passes through is farther winnowed and sifted through a finer sieve than the first. These operations are repeated five times, proceeding successively to sieves still finer and finer, and setting aside every time what remains on the sieve. What passes through the fifth sieve is rejected as sand and dust. After these operations, the whole fibrous matters remaining on the sieve are cleaned with common fanners, and women separate all the foreign matters which had not been removed before. For dividing the roots, afterwards, into different qualities, a brass sieve is made use of, whose meshes are from six to three millimetres in diameter (from $\frac{1}{4}$ th to $\frac{3}{4}$ th inch E.) What passes through the finest is rejected; and what passes through the coarsest is regarded as of the best quality. These roots, thus separated, are carried into a stove, of a construction somewhat different from the first. They are spread out in layers of about a decimetre in thickness (nearly 4 inches E.), on large lattice work frames, and the drying is known to be complete, when on taking up a handful and squeezing it, the roots break easily. On quitting the stove, the madder is carried, still hot, into a machine, where it is minced small, and a sieve separates the portion of the bark reduced to powder. This operation is repeated three or four times, and then the bolter is had recourse to. What passes through the sieve, or the brass meshes of the bolter, is regarded as com-

mon madder; and what issues at the extremity of the bolter is called the flour. Lastly, the madder which passes through the bolter is ground in a mill with vertical stones, and then passed through sieves of different sizes. What remains above is always better than what goes through.

The madder of Alsace is reduced to a very fine powder, and its coloring matter is extracted by a much longer ebullition than is necessary for the lizari of the Levant. The prepared madders ought to be carefully preserved from humidity, because they easily imbibed moisture, in which case fermentation spoils their color.

D'Ambourney and Beekman have asserted, that it is more advantageous to employ the fresh root of madder than what has been submitted to desiccation, especially by means of stoves. But in its states of freshness, its volume becomes troublesome in the dyeing bath, and uniform observation seems to prove that it ameliorates by age. Besides, it must be rendered susceptible of keeping and carrying easily.

It appears that madder may be considered as composed of two coloring substances, one of which is dun (tawny), and the other is red. Both of these substances may combine with the stuff. It is of consequence, however, to fix only the red part. The dun portion appears to be more soluble, but its fixity on stuffs may possibly be increased by the affinity which it has for the red portion.

The different additions made to madder, and the multiplied processes to which it is sometimes exposed, have probably this separation for their chief object.

The red portion of madder is soluble, but in small quantity, in water. Hence but a limited concentration can be given to its solution. If the portion of this substance be too much increased, so far from obtaining a greater effect, we merely augment the proportion of the dun part, which is the more soluble of the two.

In consequence of the Société Industrielle of Mulhausen having offered in the year 1826 large premiums to the authors of the best analytical investigation of madder, eight memoirs were transmitted to it in the year 1827. They were examined with the greatest care by a committee consisting of able scientific and practical men. None of the competitors however fulfilled the conditions of the programme issued by the society; but four of them received a tribute of esteem and gratitude from it; MM. Robiquet and Colin at Paris, Kuhlmann at Lille, and Houton-Libillardiére. Fresh premiums were offered for next year, to the amount of 2000 francs.

Every real discovery made concerning this precious root, would be of vast consequence to dyers and calico-printers. Both M. Kuhlmann, and Robiquet and Colin, conceived that they had discovered a new principle in madder, to which they gave the name *alizarine*. The latter two chemists treated the powdered madder with sulphuric acid, taking care to let it heat as little as possible. By this action the whole is carbonized, except perhaps the red matter. The charcoal thus obtained is pulverized, mixed with water, thrown upon a filter, and well washed in the cold. It is next dried, ground, and diffused through fifty parts of water, containing six parts of alum. This mixture is then boiled for one quarter of an hour, and thrown upon a filter cloth while boiling hot. The residuum is once more treated with a little warm alum water. The two liquors are to be mixed, and one part of sulphuric acid poured into them; when they are allowed to cool with occasional agitation. Flocks now make their appearance; the clear liquid is decanted, and the grounds are thrown upon a filter. The precipitate is to be washed, first with acidulated water, then with pure water, and dried, when the coloring matter is obtained in a red or purple state. This purple substance, when heated dry, gives out *alizarine*, and an empyreumatic oil, having an odor of animal matter; while a charcoally matter remains.

M. Dan. Kœchlin, the justly celebrated calico-printer of Mulhausen, has no faith in *alizarine* as the dyeing principle of madder; and thinks moreover that, were it of value, it could not be extracted on the great scale, on account of the destructive heat which would result from the acid acting upon a considerable body of the ground madder. Their *alizarine* is not a uniform substance, as it ought to be, if a proximate principle; for samples of it obtained in different repetitions of the process have produced very variable effects in dyeing. The madders of Avignon, though richer in color than those of Alsace, afford however little or no *alizarine*. In fact, *purpurine*, the crude substance from which they profess to extract *alizarine*, is a richer dye than this *pure* substance itself.

Madder contains so beautiful and so fast a color, that it has become of almost universal employment in dyeing; but that color is accompanied with so many other substances which mask and degrade it, that it can be brought out and fixed only after a series of operations more or less difficult and precarious. This dye is besides so little soluble, that much of it is thrown away in the dye-house; the portion supposed to be exhausted being often as rich as other fresh madder; hence it would be a most valuable improvement in this elegant art to insulate this tinctorial body, and make it a new product of manufacture.

Before the time of Haussmann, an apothecary at Colmar, the madder bath was subject

to many risks, which that skilful chemist taught dyers how to guard against, by introducing a certain quantity of chalk into the bath. A change of residence led Haussman to this fortunate result. After having made very fine reds at Rouen, he encountered the greatest obstacles in dyeing the same reds at Logelbach near Colmar, where he went to live. Numerous trials, undertaken with the view of obtaining the same success in his new establishment, proved that the cause of his favorable results at Rouen existed in the water, which contained carbonate of lime in solution, whilst the water of Logelbach was nearly pure. He then tried a factitious calcareous water, by adding chalk to his dye bath. Having obtained the most satisfactory results, he was not long of producing here as beautiful and as solid reds as he had done at Rouen. This practice became soon general among the calico-printers of Alsace, though in many dye-works the chalk is now replaced by lime, potash, or soda. But when the madder of Avignon is used, all these antacid correctives become unnecessary, because it contains a sufficient quantity of carbonate of lime; an important fact first analytically demonstrated by that accurate chemist M. Henri Schlumberger of Mulhausen. Avignon madder indicates the presence of carbonate of lime in it, by effervescing with dilute acids, which Alsace madder does not.

M. Kuhlman found a free acid resembling the malic, in his analysis of madders. But his experiments were confined to those of Alsace. The madders of Avignon are on the contrary alkaline, as may be inferred from the violet tint of the froth of their infusions; whereas that of the Alsace madders is yellowish, and it strongly reddens litmus paper. This important difference between the plants of these two districts, depends entirely upon the soil; for madders grown in a calcareous shelly soil in Alsace, have been found to be possessed of the properties of the Avignon madder.

The useful action of the carbonate and the phosphate of lime in the madder of Avignon, explains why madders treated with acids which remove their calcareous salts, without taking away their coloring matter, lose the property of forming fast dyes. Many manufacturers are in the habit of mixing together, and with advantage, different sorts of madder. That of Avignon contains so much calcareous matter that, when mixed with the madder of Alsace, it can compensate for its deficiency. Some of the latter is so deficient as to afford colors nearly as fugitive as those of Brazil wood and quercitron. The Alsace madders by the addition of chalk to their baths, become as fit for dyeing Turkey reds as those of Avignon. When the water is very pure, one part of chalk ought to be used to five of Alsace madder, but when the waters are calcareous, the chalk should be omitted. Lime, the neutral phosphate of lime, the carbonate of magnesia, oxyde and carbonate of zinc, and several other substances, have the property of causing madder to form a fast dye, in like manner as the carbonate of lime.

The temperature of from 50° to 60° R. (145° to 167° F.), is the best adapted to the solution of the coloring matter, and to its combination with the mordants; and thus a boiling heat may be replaced advantageously by the long continuance of a lower temperature. A large excess of the dye-stuff in the bath is unfavorable in two points of view; it causes a waste of coloring matter, and renders the tint dull. It is injurious to allow the bath to cool, and to heat it again.

In a memoir published by the Society of Mulhausen, in September, 1835, some interesting experiments upon the growth of madders in factitious soils are related by MM. Kœchlin, Persoz, and Schlumberger. A patch of ground was prepared containing from 50 to 80 per cent. of chalky matter, and nearly one fifth of its bulk of good horse-dung. Slips of Alsace and Avignon madders were planted in March, 1834, and a part of the roots were reaped in November following. These roots, though of only six months growth, produced tolerably fast dyes, nor was any difference observable between the Alsace and the Avignon species; whilst similar slips or cuttings, planted in a natural non-calcareous soil, alongside of the others, yielded roots which gave fugitive dyes. Others were planted in the soil of Palud, transported from Avignon, which contained more than 90 per cent. of carbonate of lime, and they produced roots that gave still faster dyes than the preceding. Three years are requisite to give the full calcareous impregnation to the indigenous madders of Avignon.

As to the function of the chalk, valuable observations, made long ago by M. Daniel Kœchlin, have convinced him, that the combination of two different bases with a coloring matter, gave much more solidity to the dye, in consequence, undoubtedly, of a greater insolubility in the compound. Experiments recently made by him and his colleagues above named, prove that in all cases of madder dyeing under the influence of chalk, a certain quantity of lime becomes added to the aluminous mordant. In the subsequent clearing with a soap bath, some of the alumine is removed, and there remains upon the fibre of the cloth a combination of these two earths in atomic proportions. Thus the chalk is not for the purpose of saturating the acid, as had been supposed, but of forming a definite compound with alumina, and probably also with the fatty bodies, and the coloring matter itself.

The red mordants are prepared commonly in Alsace, as follows:—The crushed alum and acetate of lead being weighed, the former is put into a deep tub, and dissolved by adding a proper quantity of hot water, when about one tenth of its weight of soda crystals is introduced to saturate the excess of acid in the alum. The acetate of lead is now mixed in; and as this salt dissolves very quickly, the reaction takes place almost instantly. Care must be taken to stir for an hour. The vessel should not be covered, lest its contents should cool too slowly.

The different mordants most generally employed for madder, are detailed under *Colors*, in *CALICO-PRINTING* and *MORDANT*.

Much mordant should not be prepared at once, for sooner or later it will deposit some sub-acetate of alumina. This decomposition takes place even in corked vials in the cold; and the precipitate does not readily dissolve again in acetic acid. All practical men know that certain aluminous mordants are decomposed by heating them, and restored on cooling, as Gay Lussac has pointed out. He observed, that by adding to pure acetate of alumina, some alum or sulphate of potash, the mixture acquires the property of forming a precipitate with a heat approaching the boiling point, and of re-dissolving on cooling. The precipitate is alumina nearly pure, according to M. Gay Lussac; but, by M. Kœchlin's more recent researches, it is shown to be sub-sulphate of alumina, containing eight times as much base as the neutral sulphate.

Madder dye.—On account of the feeble solubility of its coloring matter in water, we cannot dye with its decoction; but we must boil the dye-stuff along with the goods to be dyed; whereby the water dissolves fresh portions of the dye, and imparts it in succession to the textile fibres. In dyeing with madder, we must endeavor to fix as little of the dun matter as possible upon the cloth.

Dyeing on wool.—Alumed wool takes, in the madder bath, a red color, which is not so bright as cochineal red, but it is faster; and as it is far cheaper, it is much used in England to dye soldiers' cloth. A mordant of alum and tartar is employed; the bath of madder, at the rate of from 8 to 16 ounces for the pound of cloth, is heated to such a degree that we can just hold our hand in it, and the goods are then dyed by the wince, without heating the bath more till the coloring matter be fixed. Vitis prescribes as a mordant, one fourth of alum, and one sixteenth of tartar; and for dyeing, one third of madder, with the addition of a 24th of solution of tin diluted with its weight of water. He raises the temperature in the space of an hour to 200°, and afterwards he boils for 3 or 4 minutes; a circumstance which is believed to contribute to the fixation of the color. The bath, after dyeing, appears much loaded with yellow matter, because this has less affinity for the alum mordant than the red. Sometimes a little archil is added to the madder, to give the dye a pink tinge; but this is fugitive.

Silk is seldom dyed with madder, because cochineal affords brighter tints.

Dyeing on cotton and linen.—The most brilliant and fastest madder red is the Turkey or Adrianople. The common madder reds are given in the following way:—The yarn or cloth is boiled in a weak alkaline bath, washed, dried, and galled, by steeping the cotton in a decoction of bruised galls or of sumach. After drying, it is twice alumed; for which purpose, for every 4 parts of the goods, one part of alum is taken, mixed with 1-16th of its weight of chalk. The goods are dipped into a warm solution of the alum, wrung out, dried, and alumed afresh, with half the quantity. The acetate of alumina mordant, described above, answers much better than common alum for cotton. After the goods are dried and rinsed, they are passed through the dye-bath, which is formed of $\frac{1}{4}$ lb. of good madder for every pound of cotton; and it is raised to the boiling point by degrees, in the space of 50 or 60 minutes. Whenever the ebullition has continued a few minutes, the goods must be removed, washed slightly, and dyed a second time in the same way, with as much madder. They are then washed and passed through a warm soap bath, which removes the dun coloring matter.

Holterhoff prescribes for ordinary madder red the following proportions:—20 pounds of cotton yarn; 14 pounds of Dutch madder; 3 pounds of nut-galls; 5 pounds of alum; to which $\frac{1}{2}$ lb. of acetate of lead has been first added, and then a quarter of a pound of chalk.

In the calico-print works the madder goods are passed through a bran bath first, immediately after dyeing; next, after several days exposure to the air, when the dun dye has become oxydized, and is more easily removed. An addition of chalk, on the principles explained above, is sometimes useful in the madder bath. If bran be added to the madder bath, the color becomes much lighter, and of an agreeable shade. Sometimes bran-water is added to the madder bath, instead of bran.

Adrianople or Turkey red.—This is the most complicated and tedious operation in the art of dyeing; but it produces the fastest color which is known. This dye was discovered in India, and remained long a process peculiar to that country. It was afterwards practised in other parts of Asia and in Greece. In 1747, Ferquet and Goudard brought Greek dyers into France, and mounted near Rouen, and in Languedoc, Turkey-red

dye works. In 1765, the French government, convinced of the importance of this business, caused the processes to be published. In 1808, Reber, at Mariakirch, furnished the finest yarn of this dye, and M. Kochlin became celebrated for his Turkey-red cloth.

Process for Turkey-red.—The first step consists in clearing the yarn or cloth in alkaline baths, and dipping them in oily liquors, to which sheep's dung was formerly added. This operation is repeated several times, the goods being dried after each immersion. There next follows the cleansing with alkaline liquors to remove the excess of oil, the galling, the aluming, the maddering, the brightening or removing the dun part of the dye by boiling, at a high temperature, with alkaline liquid, and the rosing by boiling in a bath of salt of tin. We shall give some details concerning this tedious manipulation, and the differences which exist in it in the principal dye-works.

At Rouen, where the process was first brought to perfection, two methods are pursued, called the gray and the yellow course or march. In the gray, the dye is given immediately after the cotton has received the oily mordant, the gall, and the alum, as it has then a gray color. In the yellow course, it is passed through fresh oils, alum, and galls before the maddering, the cotton having then a yellow tint.

Different views have been taken of the principles of the Turkey-red dye, and the object and utility of the various steps. The most ancient notion is that of animalizing the cotton by dung and blood, but experience has proved that without any animal matter the finest color may be obtained. According to Dingler, the cotton is imbued with oil by steeping it in combinations of oil and soda; the oil is altered by repeated dryings at a high temperature; it attracts oxygen from the air, and thereby combines intimately with the cotton fibre, so as to increase the weight of the stuff. The dung, by a kind of fermentation, accelerates the oxydization, and hence crude oil is preferable to pure. In England, the mucilaginous oils of Gallipoli are preferred, and in Malabar, oils more or less rancid. The drying oils do not answer. The subsequent treatment with the alkaline liquors removes the excess of oil, which has not been oxydized and combined; a hard drying completely changes that which remains in the fibres; the aluming which follows combines alumina with the cotton; the galling tans the fibres, producing a triple compound of oil and alum, which fixes the coloring matter. The object of the other steps is obvious.

According to Wuttich, the treatment with oil opens the cotton so as to admit the mordant and the coloring matter, but the oil and soap do not combine with the fibres. In the alkaline baths which follow, the oil is transformed into soap and removed; whence the cotton should not increase in weight in the galling and aluming; the cotton suffers a kind of tanning, and the saline parts of the blood assist in fixing the madder dye.

The German process improved, according to Dingler, consists of the following operations: mordant of an oily soap or a soapy liniment, hard drying; alkaline bath, drying, steeping, rinsing away of the uncombined mordant, drying; galling, drying; aluming, drying, steeping in water containing chalk, rinsing; maddering, airing, rinsing; brightening with an alkaline boil, and afterwards in a bath containing salt of tin; then washing and drying.

The yarn or the cloth must be first well worked in a bath of sheep's dung and oil, compounded as follows:—25 pounds of sheep's dung are to be bruised in a solution of pure caustic potash of hydrometer strength 3°, and the mixed liquor is to be passed through a sieve. Two pounds of fine oil are now to be poured into 16 pounds of his ley, after which 30 pounds of coarse oil are to be added, with agitation for $\frac{1}{2}$ of an hour. Other 4 pounds of hot ley are to be well stirred in, till the whole is homogeneous. This proportion of mordant is sufficient for 100 pounds of cotton yarn, for 90 pounds of unbleached or 100 pounds of bleached cotton goods. The cotton stuff, after being well wrung out, is to be laid in a chest and covered with a lid loaded with weights, in which state it should remain for five days. At the end of 24 hours, the cotton becomes hot with fermentation, gets imbued with the mordant, and the oil becomes rapidly altered. The goods are next exposed freely to the air during the day, and in the evening they are dried in a hot chamber, exposed to a temperature of 158° F., for 6 or 8 hours, which promotes the oxydization of the oil.

The goods are now passed the second time through a soapy-oil mordant similar to the first, then dried in the air by day, and in the hot stove by night. The third and fourth oil-soap steeps are given in the same way, but without the dung. The fifth steep is composed of a ley at 2°, after which the goods must also be dried. Indeed, from the first to the fourth steep, the cotton stuff should be put each time into a chamber heated to 145° F. for 12 or 15 hours, and during 18 hours after the fifth steep.

The uncombined oil must, in the next place, be withdrawn by the *degraisage*, which consists in steeping the goods for 6 hours in a very weak alkaline ley. After rinsing and wringing, they are dried in the air, and then put into the hot stove.

The goods are now galled in a bath formed of 36 pounds of Sicilian sumach, boiled for 3 hours in 260 pounds of water, and filtered. The residuum is treated with 190 fresh pounds of water. This decoction is heated with 12 pounds of pounded nut-galls to the boiling point, allowed to cool during the night, and used next morning as hot as the hand can bear; the goods being well worked through it. They are again dried in the air, and afterwards placed in a stove moderately heated. They are next passed through a tepid alum bath, containing a little chalk; left afterwards in a heap during the night, dried in the air, and next in the stove. The dry goods are finally passed through hot water containing a little chalk, wrung out, rinsed, and then maddered.

For dyeing, the copper is filled with water, the fire is kindled, and an ounce and a half of chalk is added for every pound of madder; a pound and a quarter of madder being taken for every pound of cotton yarn. The goods are now passed through the bath, so that they penetrate to near its bottom. The fire must be so regulated, that the copper will begin to boil in the course of from $2\frac{1}{2}$ to 3 hours; and the ebullition must be continued for an hour; after which the yarn is aired and rinsed. Cloth should be put into the dye-bath when its temperature is 77° and winced at a heat of from 100° to 122° during the first hour; at 167° during the second; and at the boiling point when the third hour begins. It is to be kept boiling for half an hour; so that the maddering lasts four hours. Dinger does not add sumach or galls to the madder bath, because their effect is destroyed in the subsequent brightening, and he has no faith in the utility of blood.

After being dyed, the goods are washed, pressed, and subjected to a soapy alkaline bath at a high heat, in a close boiler, by which the dun parts of the galls and the madder are dissolved away, and the red color remains in all its lustre. This operation is called brightening. It is repeated in a similar liquor, to which some muriate of tin is added for the purpose of enlivening the color and giving it a rosy tint. Last of all, the goods are rinsed, and dried in the shade.

The *Elberfeld* process consists for 100 lbs. of the following steps:—

1. Cleaning the cotton by boiling it for four hours in a weak alkaline bath, cooling and rinsing.

2. Working it thoroughly four times over in a steep, consisting of 300 pounds of water 15 pounds of potash, 1 pailful of sheep's dung, and $12\frac{1}{2}$ pounds of olive oil, in which it should remain during the night. Next day it is drained for an hour, wrung out and dried. This treatment with the dung steep, and drying, is repeated 3 times.

3. It is now worked in a bath containing 120 quarts of water, 18 pounds of potash, and 6 quarts of olive oil; then wrung out and dried. This steep is also repeated 4 times.

4. Steeping for a night in the river is the next process; a slight rinsing without wringing, and drying in the air.

5. Bath made of a warm decoction (100° F.) of sumach and nut-galls, in which the goods remain during the night; they are then strongly wrung, and dried in the air.

6. Aluming with addition of potash and chalk; wringing; working it well through this bath, where it is left during the night.

7. Draining, and strong rinsing the following day; piling up in a water cistern.

8. Rinsing repeated next day, and steeping in water to remove any excess of alum from the fibres; the goods continue in the water till they are taken to the dyeing-bath.

9. The maddering is made with the addition of blood, sumach, and nut-galls; the bath is brought to the boil in 1 hour and $\frac{1}{2}$, and kept boiling for half an hour.

10. The yarn is rinsed, dried, boiled from 24 to 36 hours in a covered copper, with an oily alkaline liquid; then rinsed twice, laid for two days in clear water, and dried.

11. Finally, the greatest brightness is obtained by boiling for three or four hours in a soap bath, containing muriate of tin; after which the yarn is rinsed twice over, steeped in water, and dried.

Process of Haussmann.—He treats cotton twice or 4 times in a solution of aluminated potash, mixed with one thirty-eighth part of linseed oil. The solution is made by adding caustic potash to alum. He dries and rinses each time, and dries after the last operation. He then rinses and proceeds to the madder bath. For the rose color, he takes one pound of madder for one pound of cotton; for carmine red, he takes from 2 to 3 pounds; and for the deepest red, no less than 4 pounds. It is said that the color thus obtained surpasses Turkey red.

The French process, by Vitalis of Rouen.—First operation. Scouring with a soda ley, of 1° Baumé, to which there is usually added the remainder of the *white* preparation bath, which consists of oil and soda with water. It is then washed, wrung out, and dried.

In the second operation, he states that from 25 to 30 pounds of sheep's dung are commonly used for 100 pounds of cotton yarn. The dung is first steeped for some days

in a ley of soda, of 8° to 10° B. This is afterwards diluted with about 500 pints of a weaker ley, and at the same time bruised with the hand in a copper basin whose bottom is pierced with small holes. The liquor is then poured into a vat containing 5 or 6 pounds of fat oil (Gallipoli), and the whole are well mixed. The cotton is washed in this, and the hanks of yarn are then stretched on perches in the open air, and turned from time to time, so as to make it dry equably. After receiving thus a certain degree of desiccation, it is carried into the drying house, which is heated to 50° Reaumur (144° Fahrenheit), where it loses the remainder of its moisture, which would have prevented it from combining with the other mordants which it is afterwards to receive. What is left of the bath is called *avances*, and is added to the following bath. Two, or even three dung baths are given to the cotton, when it is wished to have very rich colors. When the cotton has received the dung baths, care must be taken not to leave it lying in heaps for any length of time, lest it should take fire; an accident which has occasionally happened.

The white bath is prepared by pouring 6 pounds of fat oil into 50 pints of soda water, at 1° or sometimes less, according as, by a preliminary trial, the oil requires. This bath ought to be repeated two, three, or even a greater number of times, as more or less body is to be given to the color.

To what remains of the white bath, and which is also styled *avances*, about 100 pints of soda ley of two or three degrees are added. Through this the cotton is passed as usual. Formerly it was the practice to give two, or three, or even four oils. Now, two are found to be sufficient.

The cotton is steeped for five or six hours in a tepid solution of soda, of 1° at most; it is set to drain, is then sprinkled with water, and at the end of an hour is washed, hank by hank, to purge it entirely from the oil. What remains of the water of degreissage, serves for the scouring or first operation.

For 100 pounds of cotton, from 20 to 25 pounds of galls in sorts must be taken, which are bruised and boiled in about 100 pints of water, till they crumble easily between the fingers. The galling may be done at two operations, dividing the above quantity of galls between them, which is thought to give a richer and more uniform color.

The aluming of 100 pounds of cotton requires from twenty-five to thirty pounds of pure alum, that is, alum entirely free from ferruginous salts. The alum should be dissolved without boiling, in about 100 pints of river or rain water. When the alum is dissolved, there is to be poured in a solution of soda, made with the sixteenth part of the weight of the alum. A second portion of the alkaline solution must not be poured in till the effervescence caused by the first portion has entirely ceased—and so in succession. The bath of saturated alum being merely tepid, the cotton is passed through it, as in the gall bath, so as to impregnate it well, and it is dried with the precautions recommended above. The dyers who gall at two times, alum also twice, for like reasons.

For 25 pounds of cotton, 25 pints of blood are prescribed, and 400 pints of water. Whenever the bath begins to warm, 50 pounds of madder are diffused through the bath; though sometimes the madding is given at two operations, by dividing the madder into two portions.

The brightening bath is prepared always for 100 pounds of cotton, with from four to five pounds of rich oil, six pounds of Marseilles white soap, and 600 litres of soda water of 2° B.

The rosing is given with solution of tin, mixed with soap water.

The Turkey-red dye of Messrs. Monteith and Co., of Glasgow, is celebrated all over the world, and merits a brief description here.

The calico is taken as it comes from the loom without bleaching, for the natural color of the cotton wool harmonizes well with the dye about to be given; it is subjected to a fermentative steep for 24 hours, like that preliminary to bleaching, after which it is washed at the dash wheel. It is then boiled in a ley, containing about 1 pound of soda crystals for 12 pounds of cloth. The oiling process now begins. A bath is made with 10 gallons of Gallipoli oil, 15 gallon measures of sheep's dung not indurated; 40 gallons of solution of soda crystals, of 1.06 specific gravity; 10 gallons of solution of pearl-ash of spec. grav. 1.04; and 140 gallons of water; constituting a milk-white, soapy solution of about spec. grav. 1.022. This liquor is put into a large cylindrical vat, and constantly agitated by the rotation of wooden vanes, which are best constructed on the plan of the mashing apparatus of a brewery, but far slighter. This saponaceous compound is let off as wanted by a stopcock into the trough of a padding machine, in order to imbue every fibre of the cloth in its passage. This impregnation is still more fully ensured by laying the padded cloth aside in wooden troughs during 16 or 18 days. The sheep's dung has been of late years disused by many Turkey-red dyers, both in England and France, but it is found to be advantageous in producing the very superior color of the Glasgow establishment. It is supposed, also, to promote the subsequent bleaching during the exposure

on the green; which is the next process in favorable weather, but in bad weather the goods are dried over a hot-flue.

The cloth is padded again with the saponaceous liquor; and again spread on the grass, or dried hard in the stove. This alternation is repeated a third time, and occasionally, even a fourth.

The cloth by this time is varnished as it were with oil, and must be cleansed in a certain degree by being passed through a weak solution of pearl-ash, at the temperature of about 122° F. It is then squeezed by the rollers and dried.

A second system of oiling now commences, with the following liquor:—10 gallons of Gallipoli oil; 30 gallons of soda crystals ley, of spec. grav. 1.06; and 10 gallons of caustic potash ley, of specific gravity 1.04, thoroughly diffused through 170 gallons of water. With this saponaceous liquor the cloth is padded as before, and then passed between squeezing-rollers, which return the superfluous liquor into the padding-trough. The cloth may be now laid on the grass if convenient; but at any rate it must be hard dried in the stove.

These saponifying, grassing, and drying processes, are repeated three times; whereby the cloth becomes once more very oleaginous, and must be cleansed again by steeping in a compound ley of soda crystals and pearl-ash of the spec. grav. 1.012, at the temperature of 122°. The cloth is taken out, squeezed between rollers to save the liquor, and washed. A considerable portion of the mingled alkalis disappear in this operation, as if they entered into combination with the oil in the interior of the cotton filaments. The cloth is now hard dried.

Galling is the next great step in the Turkey-red preparation; and for its success all the oil should have been perfectly saponified.

From 18 to 20 pounds of Aleppo galls (for each 100 lbs. of cloth) are to be bruised and boiled for 3 or 4 hours, in 25 gallons of water, till 5 gallons be evaporated; and the decoction is to be then passed through a searce. Two pounds of sumach may be substituted for every pound of galls. The goods must be well padded with this decoction, kept at 90° F., passed through squeezing-rollers, and dried. They are then passed through a solution of alum of the spec. grav. 1.04, to which a certain portion of chalk is added to saturate the acid excess of that supersalt; and in this cretaceous mixture, heated to 110°, the cloth is winced and steeped for 12 hours. It is then passed between squeezing-rollers, and dried in the stove.

The *maddering* comes next.

From two to three pounds of madder, ground to powder in a proper mill, are taken for every pound of cloth. The cloth, as usual in maddering, is entered into the cold bath, and winced by the automatic reel during one hour that the bath takes to boil, and during an ebullition of two hours afterwards. One gallon of bullock's blood is added to the cold bath for every 25 pounds of cloth; being the quantity operated upon in one bath. The utility of the blood in improving the color has been ascribed to its coloring particles; but it is more probably owing to its albuminous matter combining with the margarates of soda and potash condensed in the fibres.

As madder contains a dingy brown coloring matter associated with the fine red, the goods must be subjected to a clearing process to remove the former tinge, which is more fugitive than the latter. Every hundred pounds of cloth are therefore boiled during 12 hours at least, with water containing 5 pounds of soda crystals, 8 pounds of soap, and 16 gallons of the residual pearl-ash and soda ley of the last cleansing operation. By this powerful means the dun matter is well nigh removed; but it is completely so by a second boil, at a heat of 250° F., in a tight globular copper, along with 5 pounds of soap, and 1 pound of muriate of tin crystals, dissolved in a sufficient body of water for 100 pounds of cloth. The muriate of tin serves to raise the madder red to a scarlet hue. A margarate of tin is probably fixed upon the cloth in this operation.

When the weather permits, the goods should be now laid out for a few days on the grass. Some manufacturers give them a final brightening with a weak bath of a chloride of lime; but it is apt to impoverish the color.

According to the latest improvements of the French dyers, each of the four processes of oiling, mordanting, dyeing, and brightening differs, in some respects, from the above.

1. Their first step is boiling the cloth for four hours, in water containing one pound of soap for every four pieces. Their saponaceous bath of a creamy aspect is used at a temperature of 75° F.; and it is applied by the padding machine 6 times, with the grassing and drying alternations. In winter, when the goods cannot be exposed on the grass, no less than 12 alternations of the saponaceous or white bath are employed, and 8 in spring. They consider the action of the sun-beams to aid greatly in brightening this dye; but at midsummer, if it be continued more than 4 hours, the scarlet color produced begins to be impaired.

They conceive that the oiling operation impregnates the fibres with super-margarate of

potash or soda, insoluble salts which attract and condense the alumina, and the red coloring particles of the madder, so firmly that they can resist the clearing boil.

2. Their second step, the mordanting, consists first in padding the pieces through a decoction of galls mixed with a solution of an equal weight of alum; and after drying in the hot-flue, &c., again padding them in a solution of an acetate of alumina, made by decomposing a solution of 16 lbs. of alum with 16 lbs. of acetate of lead, for 6 pieces of cloth, each 32 aunes long.

3. The madding is given at two successive operations; with 4 pounds of Avignon madder per piece at each time.

4. The brightening is performed by a 12 hours' boil in water with soda crystals, soap, and salt of tin; and the *roving* by a 10 hours' boil with soap and salt of tin. Occasionally, the goods are passed through a weak solution of chloride of potash. When the red has too much of a crimson cast, the pieces are exposed for two days on the grass, which gives them a bright scarlet tint.

Process of M. Werdet to dye broadcloth and wool by madder:—

“Preparation for 24 pounds of scoured wool:

“Take 4½ pounds of cream of tartar, 4½ pounds of pure alum; boil the wool gently for 2 hours, transfer it into a cool place, and wash it next day in clear water.

“*Dyeing*.—12 pounds of Avignon madder, infused half an hour at 30° R. (100° F.) Put into the bath 1 pound of muriate of tin, let the color rose for three quarters of an hour at the same heat, and drain or squeeze the madder through canvass. The whole of the red dye will remain upon the filter, but the water which has passed through will be as deep a yellow as a weld bath. The boiler with the dye must now be filled up with clear river water, and heated to 100° F. Two ounces of the solution of the tartar and alum must be poured into it, and the wool must be turned over in it for an hour and a half, while the heat is gradually raised to the boiling point. The wool is then removed and washed. It must be rosed the following day.

“*Rosing*.—Dissolve in hot water 1 pound of white Marseilles soap; let the bath cool, and pass the wool through it till it has acquired the desired shade; 15 or 20 minutes are sufficient. On coming out of this bath it should be washed.

“*Solution of deuto-muriate of tin*:—

“2 ounces of pure muriatic acid; 4 drachms of pure nitric acid; 1 ounce of distilled water. Dissolve in it, by small portions at a time, 2 drachms of grain tin, in a large bottle of white glass, shutting it after putting in the tin. This solution may be preserved for years, without losing its virtue.”

I have inserted this process, as recently recommended by the French minister of commerce, and published by M. Pouillet in vol. i. of his *Portefeuille Industriel*, to show what official importance is sometimes given by our neighbors to the most frivolous things.

MADREPORES are calcareous incrustations produced by *polypi* contained in cells of greater or less depth, placed at the surface of calcareous ramifications, which are fixed at their base, and perforated with a great many pores. The mode of the increase, reproduction, and death of these animals is still unknown to naturalists. Living madrepores are now-a-days to be observed only in the South American, the Indian, and the Red seas; but although their polypi are not found in our climate at present, there can be no doubt of their having existed in these northern latitudes in former times, since fossil madrepores occur in both the older and newer secondary strata of Europe.

MAGISTERY is an old chemical term to designate white pulverulent substances, spontaneously precipitated in making certain metallic solutions; as magistry of bismuth.

MAGISTRAL, in the language of the Spanish smelters of Mexico and South America, is the roasted and pulverized copper pyrites, which is added to the ground ores of silver in their *patio*, or amalgamation magma, for the purpose of decomposing the horn silver present. See SILVER, for an account of this curious process of reduction.

MAGMA is the generic name of any crude mixture of mineral or organic matters, in a thin pasty state.

MAGNANIER is the name given in the southern departments of France to the proprietor of a nursery in which silk-worms are reared upon the great scale, or to the manager of the establishment. The word is derived from *magnans*, which signifies silk-worms in the language of the country people. See SILK.

MAGNESIA (Eng. and Fr.; *Bittererde*, *Talkerde*, Germ.) is one of the primitive earths, first proved by Sir H. Davy to be the oxyde of a metal, which he called *magnesium*. It is a fine, light, white powder, without taste or smell, which requires 5150 parts of cold water and no less than 36,000 parts of boiling water for its solution. Its specific gravity is 2.3. It is fusible only by the heat of the hydroxygen blowpipe. A natural hydrate is said to exist which contains 30 per cent. of water. Magnesia changes

the purple infusion of red cabbage to a bright green. It attracts carbonic acid from the air, but much more slowly than quicklime. It consists of 61.21 parts of metallic basis, and 38.79 of oxygen; and has, therefore, 20 for its prime equivalent upon the hydrogen scale. Its only employment in the arts is for the purification of fine oil, in the preparation of varnish.

Magnesia may be obtained by precipitation with potash or soda, from its sulphate commonly called Epsom salt; but it is usually procured by calcining the artificial or natural carbonate. The former is, properly speaking, a subcarbonate, consisting of 44.69 magnesia, 35.86 carbonic acid, and 19.45 water. It is prepared by adding to the solution of the sulphate, or the muriate (the *bittern* of sea-salt evaporation works), a solution of carbonate of soda, or of carbonate of ammonia distilled from bones in iron cylinders. The sulphate of magnesia is generally made by acting upon magnesian limestone with somewhat dilute sulphuric acid. The sulphate of lime precipitates, while the sulphate of magnesia remains in solution, and may be made to crystallize in quadrangular prisms, by suitable evaporation and slow cooling. Where muriatic acid may be had in profusion for the trouble of collecting it, as in the soda works in which sea salt is decomposed by sulphuric acid, the magnesian limestone should be first acted upon with as much of the former acid as will dissolve out the lime, and then, the residuum being treated with the latter acid, will afford a sulphate at the cheapest possible rate; from which magnesia and all its other preparations may be readily made. Or, if the equivalent quantity of calcined magnesian limestone be boiled for some time in *bittern*, the lime of the former will displace the magnesia from the muriatic acid of the latter. This is the most economical process for manufacturing magnesia. The subcarbonate, or *magnesia alba* of the apothecary, has been proposed by Mr. E. Davy to be added by the baker to damaged flour, to counteract its acescency.

MAGNESIAN LIMESTONE (*Dolomie*, Fr.; *Bittertalk*, *Talkspath*, Germ.), is a mineral which crystallizes in the rhombohedral system. Spec. grav. 2.86; scratches calc-spar; does not fall spontaneously into powder, when calcined, as common limestone does. It consists of 1 prime equivalent of carbonate of lime = 50, associated with 1 of carbonate of magnesia = 42.

Massive magnesian limestone, is yellowish-brown, cream-yellow, and yellowish-gray; brittle. It dissolves slowly and with feeble effervescence in dilute muriatic acid; whence it is called *Calcaire lent dolomie* by the French mineralogists. Specific gravity 2.6 to 2.7.

Near Sunderland, it is found in flexible slabs. The principal range of hills composing this geological formation in England extends from Sunderland on the northeast coast to Nottingham, and its beds are described as being about 300 feet thick on the east of the coal field in Derbyshire, which is near its southern extremity. On the western side of the Cumberland mountains magnesian limestone overlies the coal measures near Whitehaven. The stratification of this rock is very distinct, the individual courses of stone not exceeding in general the thickness of a common brick.

The lime resulting from the calcination of magnesian limestone appears to have an injurious action on vegetation, unless applied in quantities considerably less than common lime, when it is found to fertilize the soil. After two years, its hurtful influence on the ground seems to become exhausted, even when used in undue quantity. Great quantities of it are annually brought from Sunderland to Scotland by the Fifeshire farmers, and employed beneficially by them as a manure, in preference to other kinds of lime. It has been unfairly denounced, by Mr. Tennent and Sir H. Davy, as a sterilizer.

This rock is used in many places for building; indeed, our most splendid monument of Gothic architecture, York Minster, is constructed of magnesian limestone.

MAGNESIA, NATIVE (*Brucite*; *Guhr-magnesien*, Fr.; *Wassertalk*, Germ.), is a white, lamellar, pearly-looking mineral, soft to the touch. Spec. grav. 2.336; tender; scratched by calc-spar; affording water by calcination; leaving a white substance which browns turmeric paper; and, by calcination with nitrate of cobalt, becoming of a lilach hue. It consists of 69.75 magnesia, and 30.25 water. It occurs in veins in the serpentine at Hoboken, in New Jersey, as also at Swinansess, in the island of Unst, Shetland.

MAGNESITE, *Giobertite*; native carbonate of magnesia occurs in white, hard, stony masses, in the presidency of Madras, and in a few other localities. It dissolves very slowly in muriatic acid, and gives out carbonic acid in the proportion of 22 parts by weight to 42 of the mineral, according to my experiments, and is therefore an atomic carbonate. It forms an excellent and beautiful mortar cement for terraces; a purpose to which it has been beneficially applied in India by Dr. Macleod.

MAGNET, NATIVE, is a mineral consisting of the protoxyde and peroxyde of iron combined in equivalent proportions. See IRON.

MAHALEB. The fruit of this shrub affords a violet dye, as well as a fermented liquor like *Kirschwasser*. It is a species of cherry cultivated in our gardens.

MALACHITE, or *mountain green*, is native carbonate of copper of a beautiful green color, with variegated radiations and zones; spec. grav. 3.5; it scratches calc-spar, but not fluor; by calcination it affords water and turns black. Its solution in the acids deposits copper upon a plate of iron plunged into it. It consists of carbonic acid, 18.5; deutoxide of copper, 72.2; water, 9.3.

MALATES, are saline compounds with the bases, with

MALIC ACID. (*Acide malique*, Fr.; *Aepfelsaure*, Germ.) This acid exists in the juices of many fruits and plants, alone, or associated with the citric, tartaric, and oxalic acids; and occasionally combined with potash or lime. Unripe apples, sloes, barberries, the berries of the mountain ash, elder berries, currants, gooseberries, strawberries, raspberries, bilberries, brambleberries, whortleberries, cherries, anapas, afford malic acid; the houseleek and purslane contain the malate of lime.

The acid may be obtained most conveniently from the juice of the berries of the mountain ash, or barberries. This must be clarified by mixing with white of egg, and heating the mixture to ebullition; then filtering, digesting the clear liquor with carbonate of lead, till it becomes neutral; and evaporating the saline solution, till crystals of malate of lead be obtained. These are to be washed with cold water, and purified by recrystallization. On dissolving the white salt in water, and passing a stream of sulphuretted hydrogen through the solution, the lead will be all separated in the form of a sulphuret, and the liquor, after filtration and evaporation, will yield yellow granular crystals, or cauliflower concretions of malic acid, which may be blanched by redissolution and digestion with bone-black, and re-crystallization.

Malic acid has no smell, but a very sour taste, deliquesces by absorption of moisture from the air, is soluble in alcohol, fuses at 150° Fahr., is decomposed at a heat of 348°, and affords by distillation a peculiar acid, the pyromalic. It consists in 100 parts of 41.47 carbon; 3.51 hydrogen; and 55.02 oxygen; having nearly the same composition as citric acid. A crude malic acid might be economically extracted from the fruit of the mountain ash, applicable to many purposes; but it has not hitherto been manufactured upon the great scale.

MALLEABILITY, is the property belonging to certain metals, of being extended under the hammer. A table of malleability is given in the article **DUCTILITY**.

MALT; (Eng. and Fr.; *Malz*, Germ.) is barley-corn, which has been subjected to an artificial process of germination. See **BEER**.

The Quantity of Malt consumed by the undermentioned Brewers of London and its Vicinity, from 10th October, 1830, to 10th October, 1842.

Exports in 1850, 182,480 barrels; in 1851, 191,639 barrels: declared value, 1850, 558,794*l.*, in 1851, 577,874*l.*

MALT. British beer brewing is sadly oppressed by fiscal folly and ignorance. The regulations as to the manufacture of malt are embodied in the acts 7 & 8 Geo. 4, c. 52 and 11 Geo. 4, c. 17. The former act is an admirable specimen of legislative injustice; the latter was intended to ameliorate the provisions of its predecessor, and does, in a degree, effect that object. The first contains no less than 83 clauses; and the regulations in it, though frequently repugnant to the plainest principles of common sense, are, nevertheless, enforced by 106 penalties, amounting in the aggregate to the incredible sum of 13,500*l.* How much of this is negatived by the subsequent act it is not very easy to determine, though, as far as it goes, the effect of No. 2 is to stultify the regulations of No. 1. Woe to that man, however, who begins the manufacture of malt without having duly studied these incompatible acts. Having been favored with a perusal of the genuine "instructions for officers who survey maltsters," a clear insight may be had into the actual practice of the excise; for our copy is duly emblazoned with the arms of England, and marked "by authority;"—being, moreover, of so late a date as 1842, it offers unexceptionable evidence. The necessary apparatus for the production of malt is extremely simple,—that is to say, a cistern for steeping the grain; a floor in which it may be suffered to heat and vegetate; and, lastly, a stove or kiln in which the newly-formed malt may be dried. Specific size, or force, or other arrangement, there needs none; and such is actually the condition of the malt manufacture in most countries at this day. With us, however, a very different system prevails;—the cistern or steeping vessel must be of a determinate form and construction; it must have been approved of by a supervising officer; its cubical contents must have been very accurately ascertained, by actual admeasurement, and it must be placed in such a situation that the officer gauging it may have sufficient light, and a clear open space of 48 inches, at the least, above every part of such cistern, for the purpose of facilitating the process of gauging; and, lastly, if such light be an impossibility, from local obstacles, the maltster must enter into an engagement to keep, at his own expense, lamps or candles burning, for the convenience of the officer. From what we have now said, as well as from the notoriously uncertain character of grain, it might naturally be inferred, that the process of steeping would be left entirely to the judgment of the maltster, who would determine according to his experience, and the nature of the resulting phenomena, when the grain had been steeped long enough in the water and when it had not. The law, however, allows him no such privilege; whether the grain be old and dry, or new and moist, is all one,—“maltsters are required to keep their corn or grain covered with water for the full space of 40 hours, under the penalty of 100*l.*” Nor will any change occurring in the appearance of the grain, and seeming to require its immediate removal, justify or excuse the maltster in so doing, unless indeed he shall have anticipated the occurrence, by giving notice of his intention to do so in his original notice “to wet”—which must date 24 hours previously to commencing that operation,—and give the day and hour of the day for beginning the steep,—all under the usual penalty of 100*l.* Nor may he “begin to wet at any other time than between the hours of 8 in the morning and 2 in the afternoon,” under a penalty of 100*l.*, nor may he take corn or grain from any cistern at any other time than between the hours of 7 in the morning and 4 in the afternoon. To empty corn or grain out of any cistern until the expiration of 96 hours from the time of the last preceding emptying of any cistern in the establishment involves a penalty of 200*l.*; and the same infliction occurs, “if the corn or grain be not emptied out of all such cisterns at one and the same time, or within three hours after the clearing of the first cistern was commenced.”

Maltsters are not to mix, either on the floor or kiln, any corn or grain of one wetting with corn or grain of another wetting, under a penalty of 100*l.* What is termed the couch, or place in which the grain, after being steeped, is laid together for the purpose of germination, is a supplementary apparatus of excise ingenuity, and no way necessary to the success of the malting process. Here the grain, after having been gauged in the steep, is again to be gauged with great care; and if the maltster should tread or compress the couch, so as to diminish its bulk, a penalty of 100*l.* is imposed, though it is obvious that a power of loosening or compressing this couch according to its temperature would greatly improve the formation of malt. However, “all corn or grain emptied into the couch frame is to be laid flat and level by the maltster, and so kept for 24 hours at the least,” and similarly the floors are all to be placed level on pain of 100*l.* fine, so that any experimental essay at improvement is very likely to end in the Court of Exchequer. Again, it frequently happens, or rather we should say it generally happens, that too little water is absorbed by the grain during the operation of steeping; the consequence of which is, that after being removed from the couch to the floor, the grain desiccates, and, ceasing to germinate, speedily evolves a sickly odor, and becomes mouldy,—the incipient radicles at the same time drying and shrinking up for want of moisture: in fact the grain withers and perishes from the effect of drought. This condition is very frequent about the third and fourth day from the couch.

and is easily and effectually put a stop to by the application of a little water. But now comes a rather awkward dilemma for the maltster: if the grain continue on the floor without being sprinkled, it is greatly damaged or altogether spoilt; if water be sprinkled upon it to restore vitality, the law says, that "corn or grain, making into malt, must not be wetted or sprinkled with water before the expiration of 12 days, or 288 hours, after the same shall have been taken from or out of the cistern, under a penalty of 200*l*." Where, however; the steep has lasted for the full period of 50 hours and where, consequently, the want of water is less likely to be felt, the maltster may sprinkle at the end of six days, or 144 hours; but in no case less than this,—though, as we have stated, the great urgency for the sprinkling process occurs generally on the third day; and it is an undeniable fact, that in spite of the heavy risk incurred, maltsters do almost invariably sprinkle their floors at about this period, and are thus driven to the necessity of trusting in the good faith and discretion of some favorite workmen, to the infinite injury of both parties. But the vast discriminating power confided to excise officers in these matters is positively incredible. "Whenever there shall be reason to suspect, from the appearance of the grain on the floor, that it has been illegally wetted or sprinkled, the officer must give immediate notice to the maltster, or his servant, of such suspicion, and make a memorandum thereof, upon the specimen paper, and in the memorandum book, mentioning whether anything, and what was stated by such maltster, or any person on his behalf," &c. Nay, the jaundiced views of the officer are ordered to be put on record, as to an immense number of fortuitous circumstances, all of which, of course, receive an unfavorable signification: for instance, "how the kiln was loaded, and whether fed by a brisk or slow fire?—whether the house seemed in a state for running or wetting, or committing any other and what fraud?—what the trader says, and what character he bears in his concerns with the revenue?"—and so on, in the most arbitrary and unconstitutional spirit imaginable. Indeed, lest any doubt should exist concerning the opinion which the excise authorities entertain towards the trade in general, the officer is specially instructed to make sudden and unexpected returns or visits, at unusual periods, "which we call doubling on them," so as to discover any suspicious indications. Again, of the three separate gauges of malt which he may take, whether in the cistern, in the couch, or on the floor, the officer must select the largest for charging duty upon. Thus, if in the cistern he finds 78½ bushels indicated in the couch, subsequently 81½ indicated, and on the floor 83½, then the latter is preferred; and so with regard to the highest wherever found—the order being that "when the cistern or couch gauge is equal to or exceeds the floor gauge, then the best cistern or couch gauge will be the charge; but if that be less than the floor gauge, then the floor gauge will be the charge." Any accident or loss arising after the cistern gauge, is therefore thrown wholly on the maltster, who, far from being able to employ his ingenuity in the improvement of his business processes, finds himself more than fully occupied in a perpetual effort to protect his interests from the rapacious grasp of fiscal regulations conceived in the most hostile spirit to that industry by which alone they exist. The malice, carelessness, or ignorance of common workmen may at any moment subject the most honest maltster in the kingdom, not merely to charges of dishonesty but even to penal inflictions; which have ceased to carry moral degradation with them, only because of the popular belief of their gross injustice. It would be impossible, nor is it requisite, to follow out or recapitulate the innumerable annoyances to which the manufacturer of malt is subjected at present: we have thus briefly noted down a few, in order that the admirers of Bavarian and other foreign beers may take into account the very different state of the malt manufacture in this country, as compared with that brought about by an unrestricted liberty to use or apply any means which the nature of the grain, the condition of the atmosphere or other accidental circumstances, may require during the process of germination.

Before quitting this subject, there are, however, two considerations that require notice. The first of these is the peculiarly unwise regulation of allowing no drawback of the malt duty upon exported ale or beer, unless the same shall have been brewed from wort at a specific gravity of not less than 1.054. Now, in most of our colonies, and in all warm climates, beer, to be agreeable and refreshing, should be weaker than this minimum gravity. In fact, a specific gravity of 1.047 forms by far the best beverage for exportation to a tropical country, as it is not only less heady in its effects, but ferments more kindly and completely than in a heavier wort, and when well hopped is not liable to secondary fermentation. Nevertheless, beer of this kind, brewed in this country, and exported, suffers under the expense of the malt duty, and has to compete in the markets of our own colonies, as well as in the neutral markets of other countries, with ales brewed by American brewers, who pay no duty. The result, of course, is, that the supply of these weak beers has passed entirely out of the hands of English brewers.

The employment of malt in the rearing of cattle is the other consideration to which we alluded. This has been hitherto totally prevented by the excessive duty; for,

though some very absurd experiments have been made, with a view to decide the respective merits of malt and barley as nutritive agents, yet the only question which physiology points out as interesting and beneficial, remains without even the semblance of a trial. Malt, in a dry state, differs little or nothing from barley, except in the possession of an extremely minute quantity of a substance called diastase; but as diastase cannot exert its peculiar powers, excepting under the influence of water and a somewhat high temperature, the only conclusion to be drawn from the experiments made in feeding cattle on malt, is that the experimentalists were profoundly ignorant respecting the most important elements involved in the investigation. If, therefore, such experiments have proved that malt is no better than its equivalent in barley, for the fattening of cattle, we can only say that this fully equals our expectations, for there can be no doubt that the heat evolved during the malting process has robbed the grain of a portion of carbon, which is, consequently lost to the feeder of cattle. Malt cannot equal its equivalent of barley in nutritious power, unless we take advantage of the diastase it contains to render soluble, and therefore more easy of assimilation, not only its own starch, but also the farinaceous ingredients of other kinds of food. When ground malt, or a portion of diastase and water, are digested with starch, or anything containing it, at a temperature of 170° Fahr., the starch rapidly dissolves, and gradually passes, first, into gum or dextrine, and then into sugar. Thus, for example, if potatoes be mixed with a tenth of their weight of powdered malt, and the whole subjected to the action of water, treated as above, the resulting products will be gum and sugar in a soluble state; and, consequently, in that condition best of all suited to relieve or assist any digestive imperfection in the animal economy. Indeed, the process of digestion may then be said to have commenced, ere the food had reached the stomach of the animal, and the effects of diastase, heat and moisture, applied externally, substitute the action of the gastric juice within. For young or sickly animals, or those which it is desired to bring forward speedily to perfection, the use of malt, applied thus, cannot fail to ensure the most beneficial results. The nutritive powers of gum and sugar are very well known to physiologists, the first being largely used as food by the Moors, Bosjesmen of Southern Africa, and the inhabitants of Sendar in Dongolia; amongst whom "six ounces of gum are found sufficient for the daily support of an adult," according to Jackson; whilst in respect to sugar, it is quite notorious that, though the labor to the negroes, during the sugar season, is excessive, they nevertheless become extremely fat at that time from the nutritive quality of the sugar they consume. If, therefore, it is desired to ascertain the true value of malt, in aiding the digestive power of an animal, it is clear that this can be done only by taking advantage of the catalytic agency of the diastase it contains, and which seems so closely to resemble the animal principle "*pepsine*," to the influence of which the action of the gastric juice is now almost universally ascribed by chemists. Nor would there be the slightest difficulty in carrying this improvement into practice as most large farmers now prepare hot mashies for their cattle; though these are, for the most part, unwisely made from carrots, turnips, and such like vegetables as contain gum and sugar ready formed by nature; whereas the indication points to those of a starch kind, where the nutritive matter is insoluble and therefore liable to pass away from the animal unassimilated. True, indeed, the malt duty offers an impediment; but the admitted suffering of the agricultural interest is a powerful instrument of honesty in a just cause, and a drawback is no novelty to the Exchequer. There is, however, an objection of a social and moral character to be urged against the malt duty which appears altogether unanswerable. From what we have stated concerning the action of diastase, it must be obvious that a mixture of barley and malt would make quite as good a wort as malt alone; that is to say, one part of malt and seven parts of barley mashed together would afford a wort exactly resembling that from eight parts of malt alone. Thus, then, by taking advantage of his scientific knowledge, the brewer might diminish his malt duty to one-eighth, or even less; but this the law will not allow, though, in foreign countries, it may be and is done, even though the difference in cost between barley and malt is but trifling in such places. But, strange to say, that which the legislature denies to the brewer, it freely accords to the distiller, who may use a mixture of malt and barley, in any proportion he pleases; thus indicating that ardent spirits are less injurious to the social status of the lower orders than beer—a perfectly untenable line of argument, but failing which, necessitates the conclusion that little heed is taken of the moral sanity of the nation, so long as the vices of the people tend to replenish the exchequer. Having thus thrown together a few remarks calculated to explain the mode in which the excise duty on malt interferes with the industrial development of Great Britain, we refer to the article BEER for the peculiar changes which occur from the mash-tun to the finished product, as "fined" for the market. Let us here, however, notice the fact, that malt differs very largely indeed in the amount of its available constituents, which, by analysis, may be shown to range from about 62 to 70 of soluble extract per cent.—the average composition being as under:—

Moisture	-	-	-	-	-	6.5
Insoluble matter	-	-	-	-	-	26.7
Soluble extract	-	-	-	-	-	66.8

Now it is a remarkable illustration of the benumbing effect of excise interference, that, though these great differences exist, yet no process of analysis is adopted by any brewer of the present day, other than the uncertain indication of taste, and the still more equivocal guidance of weight per bushel,—for it cannot be called specific gravity. Therefore, although, in some of our large breweries not less than, perhaps, 100,000 quarters of malt are used every year (a single percentage upon which would equal the value of 1,000 quarters), yet no attempt is made, by direct experiment before buying, to determine the true worth of the article submitted for sale. The consequence of this system is not difficult to be foreseen; in a vast majority of cases a higher price is proportionally given for bad than for good malt; and the proper yield from the mash-tun being entirely unknown, there is no possibility of determining whether this operation has been well or ill-performed. A striking example of the errors induced by this random mode of valuing malt is now before us. Of three samples marked respectively Nos. 1, 2, and 3, the second was valued as 3s. better than the third; and the first as 2s. 4d. better than the second, the estimates being those of an eminent London brewer. The following table, however, which shows their real value, as found by analysis, demonstrates the total incorrectness of the above method:—

			Moisture.	Insoluble matter.	Extract.
No. 1 yielded	-	-	6.8	27.5	65.7
No. 2	-	-	9.1	24.9	66.0
No. 3	-	-	5.7	27.1	97.2

So that the sample reported to be the worst is actually that which affords the largest amount of extract, though it seems that No. 2 is the best malt; but, being a twelve-month old, its content of moisture is large. The mode of estimating the true value of malt is very easy; and, but for the circumstance that brewers are afraid of the very name of chemistry, from its vulgar association with drugs, there is little doubt that, in common with every other variable article, its worth would be determined by the unerring rules of science. The day must, however, speedily come, when this coyness can no longer prove compatible with the brewing interest; and, therefore, we proceed to describe the method of executing a chemical analysis of malt. Having ground a quantity of the malt in question to powder (and for this purpose, an ordinary coffee-mill answers perfectly), weigh out 100 grains of the powder, and expose it for half an hour to the heat of boiling water, in an oven or compartment surrounded by that fluid; at the end of this time weigh it again; the loss indicates the quantity of moisture present in the malt. While this operation is going on, 100 grains of the same powder are to be placed in a cup, with about six ounces of cold water, and then exposed to the heat of a steam-bath, with occasional stirring. This operation may continue also for half an hour, when the whole is to be thrown upon a clear linen filter; and, as soon as the wort or fluid has drained away, the residue must be well washed with boiling water; then dried and weighed. The weight represents the amount of insoluble matter, and, consequently, if, from the total weight=100, we deduct that of the moisture and insoluble matter, the remainder must represent the proportion of soluble extract, or, in other words, the saccharine value of the malt. This, as we have stated, may be taken on an average at 66 per cent.; and if we assume the quarter of malt at 324 lbs. weight, then the total saccharine extract from the quarter becomes 213.84 lbs. avoirdupois; but as this, in taking on the form of gum and sugar, chemically combines with the elements of water, so the extract, if evaporated to dryness, would reach very nearly 231 lbs.; and this reduced to the basis of a barrel, of 36 gallons, becomes, in the language of the brewer, 87 lbs. per barrel, which, however, merely means, that the wort from a quarter of malt, if evaporated down to the bulk of a barrel, or 36 gallons, would weigh 87 lbs. more than a barrel of water. As a rule, 52½ lbs. of saccharine extract indicate 20 brewers' pounds, or give a barrel of wort, having a specific gravity=1.0556 nearly.

There are some doubts as to the effect of retaining malt in a bruised or powdered state for any considerable period prior to mashing. By a few brewers this is deemed hurtful, though the majority seem to regard it as indifferent. We have made a few practical experiments on this subject, and find that, within a very extensive range, the process of mashing is rather improved than otherwise by exposing the malt to the action of the air, as, by this means, it not only attracts moisture from the atmosphere, and is thereby more easily commingled with the water in the mash-tun, but a portion of the gluten seems also oxidized by this exposure; and hence a finer and clearer wort is produced. A three months' exposure of bruised malt had not at all injured either the quantity or quality of the extract in our experiments. It might be supposed that the simplest mode of determining the value of malt would be to mash a portion with care

and then ascertain the specific gravity of the solution, but, from the circumstances previously stated, this cannot be done, as water continues to combine chemically with the extract until nothing but sugar exists, and this would require many hours' exposure to a regulated temperature; hence, the process above given is both the most exact and the most expeditious. In mashing, much depends upon the kind or strength of wort required, as well as upon the circumstance whether table beers and strong beers are brewed in the same establishment, or merely strong beers alone. Any wort weighing, in the language of the brewer, less than 15 lbs., is, properly speaking, a table or small beer wort. The wort of the common porter, drunk in this town, or London beer, weighs 20 lbs., and the strongest bottling stout is about 35. Some of the Burton and Scotch ales run, however, as high as 38 lbs. Under Barwise, the means are pointed out by which any given sample of ale or beer may be analyzed so as to determine exactly the weight of the wort from which it was brewed. At present, however, we must turn our attention to the wort as existing in, and flowing from, the mash-tun. In a general way, about 10 gallons of water may be taken for every bushel of malt in the first mash; and, after well mixing the two together, the whole should be closely covered down for three hours, ere any attempt is made to draw off the wort. It is immaterial whether the water be added to the malt, or the malt to the water; but the temperature of this latter is of great importance. In mild or warm weather a heat of 175° Fahr. is sufficient; but, in winter, 180° will be requisite, as the malt then cools down the average heat more than in summer; in either case, the temperature, after mixing, should not exceed nor fall much short of 170° Fahr. At the expiration of three hours, this wort may be withdrawn into a proper vessel, or under-back, where it must be kept warm. Its specific gravity should be about 1.092, or weigh 33 lbs. per barrel more than water. So soon as the first wort has been withdrawn (and the quantity of which is seldom more than $\frac{1}{10}$ ths of the water employed), another portion of water must be poured upon the malt, in the ratio of about eight gallons to the bushel of malt employed, and of a temperature somewhat higher than the first. After standing two hours this is drained away, like the first, when a quantity of boiling water is slowly trickled down upon the grains from an apparatus called a "sparger," until the wort, which flows away, ceases to possess any appreciable gravity beyond that of water. The worts are then mixed together, in these cases, where table beer is not made, and the whole reduced, by boiling, to the desired gravity of the beer meant to be brewed. Where table beer, however, is manufactured, the strong worts are kept apart and the weak ones alone are fermented for this purpose. In both cases, the strong beers are brewed from worts having a technical weight of from 20 to 36 lbs. per barrel. It has long been supposed, that wort, as usually manufactured, consisted chiefly of sugar, but this is a great error, for there is seldom so much as one-third of all the extract in wort saccharified. The ordinary proportion is, one part of grape-sugar and three of dextrine.

MALT KILN (*Darre*, Germ.) The improved malt kiln of Pistorius is represented, fig. 884, in a top view; fig. 885, in a longitudinal view and section; and fig. 886, in transverse section. *a a* are two quadrangular smoke flues, constructed of fire-tiles, or fire-stones, and covered with iron plates, over which a pent-house roof is laid; the whole bound by the cross-pieces *b* (figs. 885, 886.) These flues are built above a grating *c c*, which commences at *c'*; in front of *c'* there is a bridge of bricks. Instead of such a brick flue covered with plates, iron pipes may be used, covered with semi-cylindrical tiles, to prevent the malt that may happen to fall from being burned. *d d* are the breast walls of the kiln, 3 feet high, furnished with two apertures shut with iron

doors, through which the malt that drops down may be removed from time to time. *e* is a beam of wood lying on the breast wall, against which the hurdles are laid down slantingly towards the back wall of the kiln; *ff* are two vertical flues left in the substance of the walls, through which the hot air, discharged by open pipes laid in a subjacent furnace, rises into the space between the pent-house roof and the iron plates, and is thence allowed to issue through apertures in the sides. *g* is the discharge flue in the back wall of the kiln for the air now saturated with moisture; *h* is the smoke-pipe, from which the smoke passes into the anterior flue *a*, provided with a slide-plate, for modifying the draught; the smoke thence flows off through a flue fitted also with a damper-plate into the chimney *i*. *k* is the smoke-pipe of a subsidiary fire, in case no smoke should pass through *h*. The iron pipes are 11 inches in diameter, the air-flues *f*, 5 inches, and the smoke-pipe *h*, 10 inches square; the brick flues 10 inches wide, and the usual height of bricks.

MALTA; *Bitume Glutineux*, or mineral pitch. It is a soft glutinous substance, with the smell of pitch. It dissolves in alcohol, but leaves a bituminous residuum; as also in naphtha, and oil of turpentine. It seems to be inspissated petroleum.

MANGANESE (Eng. and Fr.; *Mangan*, *Braunsteinmetall*, Germ.) is a grayish-white metal, of a fine-grained fracture, very hard, very brittle, with considerable lustre, of spec. grav. 8.013, and requiring for fusion the extreme heat of 160° Wedgewood. It should be kept in closely stoppered bottles, under naphtha, like potassium, because with contact of air it speedily gets oxydized, and falls into powder. It decomposes water slowly at common temperatures, and rapidly at a red heat. Pure oxide of manganese can be reduced to the metallic state only in small quantities, by mixing it with lamp black and oil into a dough, and exposing the mixture to the intense heat of a smith's forge, in a luted crucible; which must be shaken occasionally to favor the agglomeration of the particles into a button. Thus procured, it contains, however, a little carbon.

Manganese is susceptible of five degrees of oxygenation.

1. The *protoxyde* may be obtained from a solution of the sulphate by precipitation with carbonate of potash, and expelling the carbonic acid from the washed and dried carbonate, by calcination in a close vessel filled with hydrogen gas, taking care that no air have access during the cooling. It is a pale green powder, which slowly attracts oxygen from the air, and becomes brown; on which account it should be kept in glass tubes, containing hydrogen, and hermetically sealed. It consists of 77.57 metal and 22.43 oxygen. It forms with 24 per cent. of water a white hydrate; and with acids, saline compounds; which are white, pink, or amethyst colored. They have a bitter, acerb taste, and afford with hydrogenated sulphure of ammonia a flesh-red precipitate, but with caustic alkalis, one which soon turns brown-red, and eventually black.

2. The *deutoxyde* of manganese exists native in the mineral called *Braunite*; but it may be procured either by calcining, at a red heat, the proto-nitrate, or by spontaneous oxydization of the protoxyde in the air. It is black; when finely pulverized, dark brown, and is convertible, on being heated in acids, into protoxyde, with disengagement of oxygen gas. It consists of 69.75 metal, and 30.25 oxygen. It forms, with 10 per cent. of water, a liver-brown hydrate, which occurs native under the name of *Manganite*. It dissolves readily in tartaric and citric acids, but in few others. This oxyde constitutes a bronze ground in talico-printing.

3. *Peroxyde of manganese*; *Braunstein*, occurs abundantly in nature. It gives out oxygen freely when heated, and becomes an oxydulated deutoxyde. It consists of 63.36 metal, and 36.64 oxygen.

4. *Manganic acid* forms green-colored salts, but has not hitherto been insulated from the bases. It consists of 53.55 metal, and 46.45 oxygen.

5. *Hypermanganic acid* consists of 49.70 metal, and 50.30 oxygen.

Ores of manganese.—There are two principal ores of this metal which occur in great masses; the peroxyde and the hydrated oxyde; the first of which is frequently found in primitive formations.

1. *Metalloide oxyde of manganese*; *pyrolusite*, or gray manganese ore; has a metallic lustre, a steel gray color, and affords a black powder. Spec. grav. 4.85. Scratches calc-spar. It effervesces briskly with borax at the blow-pipe, in consequence of the disengagement of oxygen gas. This is the most common ore of manganese, and a very valuable one, being the substance mostly employed in the manufacture of chloride of lime and of flint-glass. It is the peroxyde. Great quantities are found near Tavistock, in Devonshire, and Launceston, in Cornwall.

2. *Braunite*, is a dark brown substance, of a glassy metallic lustre, affording a brown powder. Spec. grav. 4.8. It scratches feldspar; but is scratched by quartz. Infusible at the blow-pipe, and effervesces but slightly when fused with glass of borax. It is the deutoxyde. It gives out at a red heat only 3 per cent. of oxygen.

3. *Manganite*, or hydroxyde of manganese; is brownish-black or iron-black, powder

brown, with somewhat of a metallic lustre. Spec. grav. 4.3. Scratches fluo: spar; affords water by calcination in a glass tube; infusible at the blow-pipe; and effervesces slightly when fused with glass of borax. It consists of about 90 of deutoxyde, and 10 of water.

4. *Hausmanite, black braunstein*; is brownish-black, affords a reddish-brown powder. Spec. grav. 4.7; scratches fluo: spar; infusible at the blow-pipe; does not effervesce when fused with borax. It is a deutoxyde. This is a rare mineral, and of no value to the arts.

5. *Barytic oxyde of manganese; fibrous wad*. It is a combination of deutoxyde and peroxyde, with some baryta.

6. *Manganese blende, or sulphuret of manganese*; has a metallic aspect; is black, or dark steel gray; spec. grav. 3.95; has no cleavage; cannot be cut; infusible, but affords after being roasted distinct evidence of manganese, by giving a violet tinge to soda at the blow-pipe. Soluble in nitric acid; solution yields a white precipitate with the ferro-cyanide of potassium. It consists of sulphur 53.65; manganese 66.35.

7. *Carbonate of manganese; dialogite*. Spec. grav. 3.4; affords a green frit by fusion with carbonate of soda; is soluble with some effervescence in nitric acid; solution when freed from iron by succinate of ammonia, gives a white precipitate, with ferrocyanide of potassium. It consists of 28 carbonic acid, 56 protoxyde of manganese, 5.4 of lime, 4.5 protoxyde of iron, and 0.8 magnesia.

8. *Hydrosilicate of manganese* is a black metallic looking substance, which yields a yellowish-brown powder, and water by calcination; is acted upon by muriatic acid, but affords no chlorine. It consists of silica 25; protoxyde of manganese 60; water 13.

9. *Ferriferous phosphate of manganese* is brown or black. Spec. grav. 3.6; scratches fluo: spar; affords by calcination a very little of an acid water which corrodes glass; very fusible at the blow-pipe into a black metalloid magnetic bead; is acted upon by nitric acid; solution lets fall a blue precipitate with ferrocyanide of potassium; which tested by soda is shown to be manganese. It consists of phosphoric acid 32.78; protoxyde of iron 31.90; protoxyde of manganese 32.60; phosphate of lime 3.2. Another phosphate called *hureaulite*, contains 38 of phosphoric acid; 11.10 of protoxyde of iron; 32.85 of protoxyde of manganese, and 18 of water.

Black wad, is the old English name of the hydrated peroxyde of manganese. It occurs in various imitative shapes, in froth-like coatings upon other minerals, as also massive. Some varieties possess imperfect metallic lustre. The external color is brown of various shades, and similar in the streak, only shining. It is opaque, very sectile, soils and writes. Its specific gravity is about 3.7. Mixed with linseed oil into a dough, black wad forms a mass that spontaneously inflames. A variety from the Hartz, analyzed by Klaproth, afforded peroxyde of manganese 68; oxyde of iron 6.5; water 17.5; carbon 1; barytes and silica 9. The localities of black wad are particularly Cornwall and Devonshire, the Hartz, and Piedmont. I have analyzed many varieties of the black wad sold to the manufacturers of bleaching salt and flint glass, and have found few of them so rich in peroxyde of manganese as the above. Very generally they contained no less than 25 per cent. of oxyde of iron, 8 or 9 of silica, about 7 of water, and the remainder amounting to only 60 per cent. of the peroxyde.

M. Gay Lussac has proposed to determine the commercial value of manganese ore, by the quantity of chlorine which it affords when treated with liquid muriatic acid. He places the manganese powder in a small retort or matrass, pours over it the acid, and the chlorine being disengaged with the aid of a gentle heat, is transmitted into a vessel containing milk of lime or potash water. This liquor is afterwards poured into a dilute solution of sulphate of indigo; and the quantity of chlorine is inferred from the quantity of the blue solution which is discolored. I pass the chlorine into test solution of indigo.

The manufacturer of flint glass uses a small proportion of the black manganese ore, to correct the green tinge which his glass is apt to derive from the iron present in the sand he employs. To him it is of great consequence to get a native manganese containing as little iron oxide as possible; since in fact the color or limpidity of his product will depend altogether upon that circumstance.

Sulphate of manganese has been of late years introduced into calico printing, to give a chocolate or bronze impression. It is easily formed by heating the black oxide, mixed with a little ground coal, with sulphuric acid. See CALICO PRINTING.

The peroxide of manganese is used also in the formation of glass pastes, and in making the black enamel of pottery. See OXALIC ACID.

The recovery of manganese in the state of peroxide for the chemical arts, in which it is so extensively consumed, has been long a desideratum in manufactures.

M. de Sussex pretends to reconvert the residuum that is left after the disengagement of chlorine or oxygen from manganese, and which is a product of little or no value, into a substance of great value, namely, that superoxide of manganese, which is peculiarly fitted, by the large proportion of oxygen it contains, to serve

the purpose of affording either chlorine or oxygen gas again, according to the process it is subsequently subjected to. The said residuary matters, after the extrication of the chlorine in the manufacture of chloride of lime, or bleaching powder, and of chlorate or hyperoxymuriate of potash, consist principally of chloride and sulphate of manganese; but as these residuums may and have been occasionally converted more or less into sulphuret of manganese when they are used to purify coal gas from its sulphur or sulphuretted hydrogen, the patentee includes not only the above sulphate and chloride, but also the sulphuret of manganese, among the waste or refuse products, which he converts into a valuable peroxide of that metal. He applies, moreover, this invention to the conversion of all oxides, carbonates, and other combinations of manganese whatever, whether native or factitious, which contain the metal in an inferior state of oxidation, into a superoxide of manganese, adapted to produce chlorine by the agency of hydrochloric acid, and oxygen by the agency either of heat alone, or of heat along with sulphuric acid.

The manner in which the said invention is to be carried into execution is as follows:

The conversion of manganese, whether combined or uncombined from a lower state of oxidation into the higher state of superoxide, is effected by two distinct operations. First, it is well known that when peroxide of manganese, called in its purest native state, pyrolusite, and also gray manganese ore, is digested with hydrochloric or muriatic acid, the oxygen of the metal combines with the hydrogen of the acid to form water, and leave the chlorine of the acid free, while the manganese, thus partially stripped of its oxygen, combines with the rest of the hydrochloric acid to form a muriate of manganese. Likewise, when more or less dilute sulphuric acid, common salt (chloride of sodium), and peroxide of manganese, are so mixed and treated as to be made to react on one another the hydrochloric acid, which is disengaged, is converted by the oxygen of the manganese into water and chlorine, while both the soda produced from the common salt, and the partially deoxidized manganese, combine with the sulphuric acid into sulphate of soda and sulphate of manganese. He converts either the chloride, sulphate, sulphuret, or carbonate, into a sesquioxide or deutoxide of manganese, by one or other of the three following processes:—First, he subjects dried chloride of manganese to a strong heat, produced either by the united action of burning fuel, and a jet or jets of an oxy-hydrogen blowpipe, or of a stream of atmospheric air thrown upon the burning fuel by a fan or other suitable impulsive power, thus forming a kind of blowpipe or blast-furnace, in which the chemical decomposition and reaction are rendered quicker and more complete. The furnace is constructed like an ordinary reverberatory furnace, with the addition of a box or chest of iron open at top, set in the fire-place, close to the bridge, which box is filled with iron turnings, borings, or other small fragments of iron, upon which, in their strongly ignited state, water is allowed to trickle or drop down slowly from a pipe, so as to be decomposed, and to disengage a stream of hydrogen, which is impelled over the bridge of the furnace upon the hearth by means of a fan or other blowing machine acting at the entrance or door of the fire-place. The manner in which the furnace is regulated is as follows:—The fuel, either common coals, coke, anthracite, wood, turf, &c., is first lighted upon the grate, and being subjected to the blast of air, soon creates such a temperature as to raise the box of iron turnings to a red-white heat, in which state the water being allowed to trickle down into the said box, is decomposed with the copious disengagement of hydrogen gas. The chloride of manganese may be exposed on the hearth of the reverberatory furnace either in a more or less concentrated liquid state, or in a dry state, to the action of the intensely powerful flame, generated as above described, and becomes thereby decomposed by the hydrogen, with the disengagement of its chlorine in the state of hydrochloric acid or muriatic acid gas, while the remaining protoxide of manganese becomes at the same time oxidized into the deutoxide. The hydrochloric acid gas disengaged is condensed by means of vaults or large chimneys, containing wet coke or flint nodules in the way often practised in soda manufactories. Instead of the above-described hydrogen flame, he employs sometimes a simple reverberatory furnace with ordinary fuel, either with or without blast, in which he resolves the chloride of manganese into hydrochloric acid and peroxide of manganese, but he prefers the compound flame of hydrogen and ordinary fuel.

In his second process, instead of acting on chloride of manganese by the flame of combustible matter on the hearth of a furnace, he subjects the chloride of manganese, put into fire-clay retorts, to an intense heat, by which he expels the chlorine partly in the state of hydrochloric acid, and partly of chlorine, and the manganese left in the retorts may be afterwards peroxidized by a process to be presently described.

In his third process he mixes together chloride of manganese and carbonate of lime, or quicklime, in the proper equivalent proportions for mutual decomposition, and he subjects that mixture to the strong heat of the above-described compound hydrogen flame, whereby he obtains a mixture of chloride of calcium (muriate of lime), and oxide

of manganese, which he peroxidizes by a process about to be described. Magnesia, or magnesian limestone, may be substituted for lime, or its carbonate, in this process. When the carbonate of lime is used with rather too low a heat in the furnace, carbonate of manganese may be formed. In all cases, the resulting mixture of chloride of calcium or magnesium, and oxide of manganese is to be treated with water, so as to dissolve out the said chlorides, and leave the oxide of manganese.

The following is the plan of decomposing sulphate of manganese, however formed, so as to obtain from it an oxide of manganese, to be peroxidized by an after process:—

He mixes the sulphate of manganese with sawdust, ground coke or charcoal, or any like combustible matter, only in such proportion as to be capable of decomposing the sulphuric acid present, when the mixture is subjected to a strong calcining heat in retorts of iron, or preferably of fire-clay, whereby he obtains a sulphuret of manganese, mixed with more or less oxide of manganese. He finishes this operation by introducing into the said residuary mixture, fragments of coke, charcoal or coal, and continuing the application of heat for some time, while the mouth of the retort is left open, whereby he desulphurates the manganese in a greater or less degree, and converts its sulphuret into an oxide. In case any salt, or other compound of soda, should have been mixed with the sulphate of manganese, the soda compound is to be separated from the manganese by means of water, after the above-described calcination in the retorts. The sulphuret of manganese sometimes produced in coal gas works, as a residuum of the purification of the gas, may be desulphurated in retorts as above described, or preferably by exposing it mixed with pieces of coke, charcoal, coal or wood, on the hearth of the above-described reverberatory hydrogen furnace. The coke, &c., should be used not in powder, but in distinct pieces, whereby it may be readily separated from the oxide of manganese afterwards, either by a sieve or other suitable means.

The following is his manner of performing the second operation, or series of operations, whereby he converts the deutoxide of manganese produced in the before-described processes, as also all lower oxides and the carbonated oxide of manganese, whether natural or factitious, into a superoxide fit for affording chlorine by the action of hydrochloric acid, and oxygen by heat; and he produces the said peroxidization in one or other of the three following ways. First, he converts the said oxides or carbonates from their lower to the much higher state of oxidation of an acid of manganese, by subjecting a mixture of them with alkaline matters, such as potash or soda, either caustic or carbonated, on the hearth of a reverberatory furnace, to the joint agency of heat and atmospherical oxygen, which may or may not be impelled and diffused by mechanical means. He finds that about one part of the oxide or carbonate of manganese, mixed with about three parts of alkaline matter, forms a suitable proportion for the production of an acid of manganese. The said mixture fuses with the production of a manganate or permanganate of potash or soda, according as one or other alkali has been used in the mixture. The fused mass is run or laded out of the furnace, and when cooled is dissolved in hot water. This solution, of what is sometimes called chameleon mineral, on being exposed freely to the air, becomes decomposed, by the absorption of carbonic acid gas, into peroxide of manganese, which precipitates in a black powder, and carbonated alkali which remains in solution. Where carbonic acid can be conveniently procured at a very cheap rate, the above described decomposition of the chameleon mineral may be promoted by a due application of the said acid gas. Or, otherwise, the alkaline bicarbonates obtained from a preceding decomposition of chameleon mineral may be employed for decomposing a fresh made solution of the said chameleon, whereby a precipitate of peroxide of manganese is immediately obtained. The supernatant alkaline liquor is in all cases decanted or run off, and reserved for subsequent use. He also decomposes chameleon mineral with the production of peroxide of manganese by the action of various organic products, such as starchy or gummy matters, but he greatly prefers to effect the desired production of peroxide of manganese by carbonic acid gas, or an alkaline bicarbonate. His second method of producing peroxide of manganese from its lower oxide or carbonate, consists in subjecting a mixture of about one equivalent chemical proportion of either of these, and about one equivalent of lime, to the chlorine expelled by heat from chloride of manganese, contained in the retort, as heretofore described. Or, by treating one equivalent proportion of that lower oxide of manganese, called by chemists sesquioxide or deutoxide, with one-half of an equivalent proportion of aqueous or liquid hydrochloric acid, he obtains simultaneously one-half of an equivalent proportion of protochloride of manganese in solution, and one-half an equivalent of peroxide in the state of a black powder. A like reaction, with the production of a solution of protochloride of manganese, and black peroxide, may be effected by treating the said sesquioxide with aqueous hydrochloric acid in one vessel, and transmitting therefrom the chlorine disengaged into another vessel, containing a like sesquioxide in a moist state.

The third method of converting into peroxide of manganese its lower oxide or carbonate consists in directing over the surface of either of these, in a moist state, the deutoxide of azote, frequently called nitrous gas, which is obtained as a waste product in certain chemical operations, as in the manufacture of oxalic acid, or nitrate of lead, or of copper, &c.

In this case, the nitrous gas becomes reduced to a lower state of oxidation, and by imparting oxygen to the lower oxide of manganese, converts it into peroxide

MANGANESE, OXIDE OF; for a simple method of ascertaining the value of this substance in the production of chlorine, and the manufacture of the chlorides and chlorates, see **CHEMISTRY SIMPLIFIED**.

MANGLE. (*Calandre*, Fr.; *Mangel*, Germ.) This is a well known machine for smoothing table cloths, table napkins, as well as linen and cotton furniture. As usually made, it consists of an oblong rectangular wooden chest, filled with stones, which load it to a degree of pressure that it should exercise upon the two cylinders on which it rests, and which, by rolling backwards and forwards over the linen spread upon a polished table underneath, render it smooth and level. The moving wheel, being furnished with teeth upon both surfaces of its periphery, and having a notch cut out at one part, allows a pinion, uniformly driven in one direction, to act alternately upon its outside and inside, so as to cause the reciprocating motion of the chest. This elegant and much admired English invention, called the mangle-wheel, has been introduced with great advantage into the machinery of the textile manufactures.

Mr. Wareup, of Dartford, obtained a patent several years ago for a mangle, in which the linen being rolled round a cylinder revolving in stationary bearings, is pressed downwards by heavy weights hung upon its axes, against a curved bed, made to slide to and fro, or traverse from right to left, and left to right alternately.

Mr. Hubie, of York, patented in June, 1832, another form of mangle, consisting of three rollers placed one above another in a vertical frame, the axle of the upper roller being pressed downwards by a powerful spring. The articles intended to be smoothed are introduced into the machine by passing them under the middle roller, which is made to revolve by means of fly wheel; the pinion upon whose axis works in a large toothed wheel fixed to the shaft of the same roller. The linen, &c. is lapped as usual in protecting cloths. This machine is merely a small **CALENDER**.

MANIFOLD BELL-PULL. (*Exhibition.*) 45 Bryden and Sons, Rose Street, Edinburgh, Inventors and Manufacturers.—A manifold bell-pull constructed upon an entirely new plan, by which one pull is made to ring bells in any number of rooms. When the pointer is placed opposite to any name on the dial plate, and knob pulled out, the bell is then rung in the room indicated.

An improved circular telegraph bell having two dials, numbered in the same manner, by means of which eight different clerks or workmen may be called.

An air signal mouth piece and bell, by blowing into the mouth-piece the bell is rung, at any distance less than 1,000 feet. This is an improved method of ringing a bell in places too distant or not suited for working cranks and wires.

A single voice tube mouth-piece and bell-pull. When drawn out the tube orifice is opened, and the signal bell being rung, the attendant is called to the other end of the tube.

A revolving mouth-piece for voice tubes, with bell-pull combined; contrived so that one mouth-piece connects with six or any greater number of voice tubes, and at the same time with a similar number of bells.

Specimen of a self-closing valve mouth-piece for voice tube; and of a spring covered mouth-piece for voice tube.

MANIOC, is the Indian name of the nutritious matter of the shrub *jatropha manihot*, from which *cassava* and *tapioca* are made in the West Indies.

MANNA, is the concrete saccharine juice of the *Fraxinus ornus*, a tree much cultivated in Sicily and Calabria. It is now little used, and that only in medicine.

MANUFACTURING INDUSTRY, DURING THE LAST AND PRESENT CENTURY, by Wm. Fairbairn, Esq., F. R. S., Member of the Institute of France.—If we take, I will not say a statistical, but a very cursory view of the recent position of Manchester and the surrounding districts, and compare it with what it was at the close of the last and the commencement of the present century, we shall find that at that period the useful and industrial arts were comparatively of little importance. We shall also find that the grafts of a new, and above all others an important branch of manufacturing industry springing into existence. I have no returns of the state of our manufacturing industry at that period, but the writings of one of our earliest and most intelligent spinners, to whom this country is indebted for many improvements in machinery, Mr. John Kennedy, informs us, that the spinning of cotton yarn antecedent to the year 1768, was of an exceedingly limited description. That gentleman in his account of the rise

and progress of the cotton trade, stated that the hand-loom as a machine remained stationary for a great number of years without any attempt at improvement until 1750, when Mr. John Kay, of Bolton, first introduced the fly-shuttle, and that the spinning of cotton yarn from that period, and for many years previous, was almost entirely performed by the family of the manufacturer at his own house. This united and simple process went on till it was found necessary to divide their labors, and to separate the weaving from the spinning, and that again from the carding and other preparatory processes. This division of labor as Mr. Kennedy truly says, led to improvements in the carding and spinning, "by first introducing simple improvements in the hand instruments, with which they performed these operations, till at length they arrived at a machine, which, though rude and ill-constructed, enabled them considerably to increase their produce." Thus it was that improvements, and the division of labor, first led to the factory system, and that splendid and extensive process which at the present moment and for many years to come will affect the destinies of nations. From 1750 to 1770, when Mr. Hargreaves, of Blackburn, first introduced his spinning jenny, (by means of which a young person could work from ten to twenty spindles instead of one), there was little or no change, but a very material alteration took place shortly after the introduction of these improvements, which were immediately followed by Mr. Arkwright's machinery for carding and roving. These accompanied by the introduction of Mr. Crompton's mule, in 1780, may be justly considered to constitute the origin of the factory system, which has now grown to such colossal dimensions, as to render it one of the most important and most extensive systems of manufacture ever known in the history of ancient or modern times. Mr. Arkwright built his first mill at Cromford in Derbyshire (I again quote from Mr. Kennedy) "in 1771. It was driven by water, but it was not till 1790, or some time after, when the steam engine of Watt came into use, that the cotton trade advanced at such an accelerated speed, as to render its increase and present magnitude almost beyond conception. This immense extension is not only a subject of deep interest to the philosopher and statesman, but one which is likely to furnish a large field of observation for the future historian of his country." I will not trouble you with the statistics of the cotton trade as it now exists, but simply observe, as many of you are doubtless better informed on this subject than myself, that I am within the mark, when I state that no less than 31,500 bales of cotton are consumed weekly, in the two kingdoms, England and Scotland; that nearly 21,000,000 spindles are almost constantly in motion, spinning upwards of 105,000,000 hanks, or 50,000,000 miles of yarn per day—in length sufficient to circumscribe the globe 2,000 times. Out of this immense production about 131,000,000 pounds of yarn are exported; the remainder is converted into cloth, lace and other textile fabrics. This marvellous increase, this immense extent of production, could not be effected without considerable changes in the prospects of the moral as well as the physical condition of society. It has entirely changed the position of the resident population of the district; and the secluded valleys, farm-houses and cottages, the beauties of a Lancashire landscape of the last generation, are rapidly giving way to the conversion of villages into populous towns, with innumerable erections which resound with the busy hum of the spindle and the shuttle. Along with these changes we see a new generation springing into existence, factories, steam-engines, and tall chimneys rising in every direction, and the noise and smoke which meet the eye and the ear of the stranger at every step give evidence of the activity and prosperity of the industrious hive, which at some future time in English history will announce to succeeding generations the inventions and the discoveries of the nineteenth century.

In this attempt to place before you a short account of the use and progress of our national industry, I must not forget that yarn, however finely or dexterously spun is not cloth; and here we enter upon another, and equally ingenious process. The yarn must be woven before it is fit for use, and we shall be weaving one of the most interesting as well as elaborate operations of the useful arts. I need not inform you that the ancient Hindoos, Egyptians, and probably the early Chinese converted their yarn into cloth. The Indian and Oriental department of the Great Exhibition exhibited the mode and primitive character of their looms and other implements, which have been handed down from generation to generation from the earliest periods, without change or improvement to the present day. Looms of this rude construction were introduced into Europe during the first glimpses of civilization, and for many centuries even the most advanced nations were content to use the same instruments, almost without improvement, until the introduction of the flying shuttle and the subsequent invention of Hall and Arkwright opened a new and untrodden field for improvements in every department of art and manufacture. Power looms at that period were unknown, and although attempts were made by Mr. Cartwright, as early as 1774, to convert the hand loom into a machine to be moved by power, it was not until the beginning of the present century that the power-loom assumed its present form, and presented that intelligence of

structure which rendered it self-acting, and enabled it to compete with the hand-loom weaver. From that time (about 1810 or 1812), we may date the commencement of that increase to which that important branch of our manufacture was extended. The improvements introduced by Mr. Bennet Woodcroft and other for weaving twills and similar fabrics created new expedients and applications, and greatly increased the demand of this description of manufactures, whilst the inventions of Jacquard for weaving figured cloth startled every one with their extreme ingenuity and beauty, and accomplished the perfection of machinery for the production of textile fabrics. The increase and extent of cloth manufactured from power-looms may be estimated from official returns, kindly furnished by Mr. Leonard Horner. There are now at work in the United Kingdom above 250,000 power-looms. Now as each loom will upon the average form five to six pieces of cloth per week, each piece 28 yards long, say 25 yards a day per loom, we have 250,000, which multiplied by 25 gives 6,250,000 yards, or 3,551 English miles of cloth per day, the distance between Liverpool and New York.

Only think of the importance and extent of a manufacture that employs upwards of 12,000 hands in weaving alone, supplying from that source (the power-loom) an annual produce of cloth that would extend over a surface in a direct line of upwards of 1,000,000 miles.

But although much has been done, much has yet to be accomplished before the supply equals the demand. It must appear obvious to those who have studied and watched the unwearied invention and continued advancement which has signalized the exertions of our engineering and mechanical industry. But neither difficulties nor danger, however formidable, can stand against the indomitable spirit, skill, and perseverance of the English engineer; nor will it be denied that the ingenuity and never-failing resources of our mechanical population are not only the sinews of our manufactures, railways, and steamboats, but the pride and glory of our own country.

It is for this important class, that I have ventured to address you, and I trust the time is not far distant, when we shall witness establishments suitable for their education, such as will teach them to reason and to think, and to impart that knowledge essential to a more correct acquaintance with physical truth, and a clearer conception of the varied manipulations of those arts in which consist the true interests of the country.—*Lecture at Manchester.*

MANURE. A patent for an excellent article of this kind was obtained in May, 1842, by J. B. Lawes, Esq., for a full description of which the reader is referred to the articles *COPROLITES*. He decomposes bones, apatite, and other subphosphates of lime by mixing them in powder with as much sulphuric acid as will liberate enough of the phosphoric to dissolve the phosphate of lime. The free phosphoric acid is thereby ready to combine with the various alkaline earths contained in the soil, while the phosphate of lime is brought to a state of more minute division than is possible by mechanical means. Mr. Lawes also proposes to mix the above soluble superphosphate with such alkalis as are deficient in the soil, and thus to form a manure adapted to fertilize it. His third improvement in manure is the formation and application of a liquor of flints, for such soils as are deficient in soluble silica. The last compound he considers to be valuable for grounds much cropped with wheat and other cereals that require a good deal of silica for their growth.

It is greatly to be regretted, that this most important subject of scientific research, has hitherto been treated too much in a one-sided manner; that is, either by individuals little conversant with practical farming, or by farmers little acquainted with the nature of soils, and the changes produced on them by the cultivation of different orders of plants.

Under the auspices of the British Association, Professor Liebig, in the year 1840, first promulgated his views on agriculture, from which date we may trace a spirit of investigation into it, such as had not previously existed in this country. Among other laborers in this field, we must state that Mr. J. B. Lawes, of Rothamstead, in Hertfordshire, was occupied several years prior to the first edition of Professor Liebig's work, in investigating the action of different chemical combinations when applied as manures, to the most important crops of the farm; and having ever since continued his experimental researches with all the lights of science, with which he is familiar, aided by Dr. J. H. Gilbert, a skilful analytical chemist, he has been able to arrive at conclusions of greater value and precision than the merely theoretical determinations of the German professor. In the course of this inquiry, the whole tenor of the results of Messrs. Lawes and Gilbert, and also of information derived from intelligent agricultural friends, upon every variety of land in Great Britain, has forced upon them opinions different from those of Professor Liebig, on some important points; and more especially, in relation to his so-called "mineral theory," which is embodied in the following sentence to be found at page 211. of the third edition of his work on Agricultural Chemistry; where he says "the crops on a field diminish or increase in exact proportion to the diminution or increase of the mineral substances conveyed to it in manure."

Of the vast importance, both in a scientific and a practical point of view, of correct

ideas on the subject here at issue, a judgment may be formed from the manner in which the professor himself speaks of the mineral theory in the new edition of his lectures on chemistry. Thus at page 482, he says of the agriculturists of England that "sooner or later they must see that in the so-called mineral theory in its development and ultimate perfection lies the whole future of agriculture."

"Looking upon the subject in a chemical point of view only, it would seem that an analysis of the soil upon which crops were to be experimentally grown, as well as a knowledge of the composition of the crop should be the first points ascertained, with the view of deciding in what constituents the soil was deficient; and at the commencement of our more systematic course of field experiments, the importance of these points was carefully considered. When we reflect, however, that an acre of soil six inches deep may be computed to weigh about 1,344,000 lbs. (though the roots of plants take a much wider range than this), and taking the one constituent of ammonia or nitrogen as an illustration, that in adding to this quantity of soil a quantity of ammoniacal salt, containing 100 lbs. of ammonia, which would be an unusually heavy and very effective dressing, we should only increase the percentage of ammonia in the soil by 0.0007, it is evident that our methods of analysis would be quite incompetent to appreciate the difference between the soil before and after the application,—that is to say, in its state of exhaustion, and of highly productive condition, so far as that constituent is concerned; and from our knowledge of the effects of this substance on wheat, we may confidently assert that the quantity of it supposed above would have given a produce at least double that of the unmanured land. The same kind of argument might, indeed, be adopted in reference to the more important of those constituents of a soil which are found in the ashes of the plants grown upon it, and we determined, therefore, to seek our results in another manner. Indeed, the imperfection of our knowledge of the productive quality of a soil, as derived from its percentage composition, has been amply proved by the results of analysis which have been published during the last ten years; and in corroboration we need only refer to the opinions of Professor Magurs on this subject, who, in his capacity of chemist to the 'Landes-Oekonomie Kollegium' of Prussia, has published the results of many analyses of soils. The truth is, that little is as yet known of what a soil either is, or ought to be, in a chemical point of view; but when we call to mind the investigations of Professor Mulder, in relation to the organic acids found in soils, and of Mr. Way and others, as to the chemical and physical properties of soils, in relation to the atmosphere, and to saline substances exposed to their action in solution, we may at least anticipate for chemistry that she will ere long throw important light on this interesting but intricate subject.

"In our field experiments, then, we have been satisfied with preserving specimens of the soils which were to be the subjects of them, and have sought to ascertain their deficiency in regard to the production of different crops, by means which we conceive to be not only far more manageable, but in every way more conclusive and satisfactory in their result. To illustrate,—what is termed a rotation of crops is at least of such universality in the farming of Great Britain, that any investigation in relation to the agriculture of that country may safely be grounded on the supposition of its adoption. Let us, then, direct attention for a moment to some of the chief features of rotations. What is called a *course* of rotation is the period of years which includes the circle of all the different crops grown in that rotation or alternation. The crops which thus succeed each other, and constitute a rotation, may be two, three, four, or more, varying with the nature of the soil and the judgment of the farmer; but whatever *course* be adopted, no individual crop—wheat, for example, is grown immediately succeeding one of the same description, but it is sown again only after some other crops have been grown, and at such a period of the rotation, indeed, as by experience it is known that the soil will, by direct manure or other means, have recovered its capability of producing a profitable quantity of the crop in question.

"On carefully considering these established and well-known facts of agriculture, it appeared to us that, by taking soils either at the end of the rotation, or at least at that period of it when the ordinary course of farming farm-yard manure would be added before any further crop would be grown, we should then have the soils in what may be termed a *normal*, or, perhaps better still, a *practically and agriculturally exhausted* state.

"Now, if it is found, in the experience of the farmer, that land of any given quality with which he is well acquainted, will not, when in this condition of practical exhaustion, yield the quantity he usually obtains from it of any particular crop, but that after applying farm-yard manure it will do so, it is evident that if we supply to different plots of this *exhausted land* the constituents of farm-yard manure both individually and combined, and if by the side of these plots we also grow the crop both without manure of any kind and with farm yard manure, we shall, in the comparative results obtained, have a far more satisfactory solution of the question as to what constituents were, in this ordinary course of agriculture, most in defect in respect to the proportion of the particular

crop experimented upon, than any analysis of the soil could have given us. In other words, we should have before us very good ground for deciding to which of the constituents of the farm-yard manure the increased produce was mainly due on the plot provided with it, in the case of the particular crops; not so, however, unless the soil had been so far exhausted by previous cropping as to be considered *practically* unfit for the growth of the crop without manure. We lay particular stress on this point, because we believe that the vast discrepancy in the results of comparative trials with different manures, by different experiments, arise more from irregularity in what may be called the *floating* capital of the soil than from irregularities in the original character of the soil itself, or from any other cause, unless we include the frequent faulty methods of application.

"It is then, by this *synthetic* rather than by the analytic method that we have sought our results; and in the carrying out of our object we have taken *wheat* as the type of the cereal crops, *turnips* as the type of the *root crops*, and beans as the representative of the *leguminous* corn crop most frequently entering into rotation; and having selected for each of these a field which, agriculturally considered, was *exhausted*, we have grown the same description of crop upon the same land, year after year, with different chemical manures, and in each case with one plot or more continuously unmanured, and one supplied every year with a fair quantity of farm-yard manure. In this way 14 acres have been devoted to the continuous growth of wheat since 1843, 8 acres to continuous growth of *turnips* from the same date, and, 5 to 6 acres to that of leguminous corn crops since 1846. And of field experiments, beside these which amount in each year to from 30 to 40 on wheat, upwards of 90 on turnips, and 20 to 30 on beans, others have been made, viz., some on the growth of clover, and some in relation to the chemical circumstances involved in an actual course of rotation, comprising turnips, barley, clover, and wheat, grown in the order in which they are here stated.

"It may be stated, too, that in addition to these experiments on wheat, and the other crops usually grown upon the farm, as above referred to, we have for several years been much occupied also with the subject of the feeding of animals, viz. bullocks, sheep, and pigs,—as well as in investigating the functional actions of the growing plant in relation to the soil and atmosphere; and in connection with each of these subjects much laboratory labor has constantly been in progress.

"The scope and object of our investigation has been therefore to examine in the field, the feeding shed, and the laboratory, into the chemical circumstances connected with the agriculture of Great Britain in its four main features; namely—

"First, the production of the cereal grain crops; secondly, that of root crops; thirdly, that of the leguminous corn and fodder crop; and fourthly, and lastly, that of the consumption of food on the farm for its double produce of meat and manure.

"So much then for the rationale and general plan of the experiments themselves, and we now propose to call attention to some of the results which they have afforded us.

"Hitherto, only part of the results of the wheat experiments of the harvests of 1844, 1845, and 1846, and of these seasons only, have been published; those on turnips, only for the seasons 1843, 1844, and 1845; those on the leguminous crops not at all as yet; and those on feeding, only as far as sheep are concerned, and chiefly too in relation to the one point only of the increase of *live weight* obtained from a given quantity of food, or its constituents. Of the laboratory results, but few have been given in relation to any of these branches up to the present time. The vast accumulation of results, indeed, will necessarily still further postpone the publication of them in any extended form; and hence it seems the more desirable to take advantage of the present opportunity to attempt to bring together into one view some of the general indications which have been arrived at in relation to a few important points.

"With this view, it is to the field experiments on wheat that we shall chiefly confine our attention on this occasion; for wheat, which constitutes the principal food of our population, is with the farmer the most important crop in his rotation, all others being considered more or less subservient to it; and it is, too, in reference to the production of this crop in agricultural quantity that the mineral theory of Baron Liebig is perhaps more prominently at fault than in that of any other. It is true, that in the case of vegetation in a native soil, manured by art, the mineral constituent of the plants being furnished from the soil, the atmosphere is found to be a *sufficient* source of the nitrogen and carbon; and it is the supposition that these circumstances of *natural vegetation* apply equally to the various crops when grown *under cultivation* that has led Baron Liebig to suggest that, if by artificial means we accumulate within the soil itself a sufficiently liberal supply of those constituents found in the ashes of the plant, essentially soil constituents, we shall by this means be able in all cases to increase thereby the assimilation of the vegetable or atmospheric constituents in a degree sufficient for agricultural purposes. But agriculture is itself an *artificial* process; and it will be found that, as regards the production of wheat more especially, it is only by the accumulation within the soil itself

of nitrogen *naturally* derived from the atmosphere, rather than of the peculiarly soft constituents, that our crops of it can be increased. Mineral substances will, indeed, materially develop the accumulation of vegetable or atmospheric constituents when applied to *some* of the crops of rotation; and it is thus chiefly that these crops become subservient to the growth of the cereal grains, but even in these cases it is not the constituents, *as found collectively in the ashes of the plants to be grown*, that are the most efficient in this respect; nor can the demand which we find thus made for the production of crops in *agricultural quantity* be accounted for by the mere idea of supplying the *actual* constituents of the crop. It would seem, therefore, that we can only arrive at correct ideas in agriculture by a close examination of the actual circumstances of growth of each particular crop when grown under cultivation. We now turn to the consideration of our experiments upon this subject. It has been said that all the experimental fields were selected when they were in a state of agricultural exhaustion. The wheat fields, however, after having been manured in the usual way for turnips at the commencement of the previous rotation, had then grown barley, peas, wheat, and oats, without any further manuring; so that when taken for experiment in 1844, it was, as a grain-producer, considerably more exhausted than would ordinarily be the case. It was, therefore, in a most favorable condition for the purposes of our experiments.

"In the first experimental season, the field of 14 acres was divided into about 20 plots, and it was by the *mineral theory* that we were mainly guided in the selection of manures: mineral manures were therefore employed in the majority of cases. *Ammonia*, on the other hand, being then considered as of less importance, was used in a few instances only, and in these in very insignificant quantities. Rape-cake, as being a well recognised manure, and calculated to supply, besides some minerals and nitrogen, a certain quantity of carbonaceous substance in which both corn and straw so much abound, was also added to one or two of the plots.

TABLE 1.—Harvest 1844. Summary.

Description of the Manures.	Dressed Corn per Acre, in Bushels and Pecks.	Total Corn per Acre, in lbs.	Straw per Acre, in lbs.

" 2. 14 tons of farm-yard manure - -	16 0	923	1120
" 4. The ashes of 14 tons of farm manure -	22 0	1276	1476
" 8. Minimum produce of 9 plots, with artificial mineral manures - - -	16 0	888	1104
Superphosphate of lime 350 lbs. -	16 1	980	1160
Phosphate of potass 364 lbs. -			
Plot 15. Maximum produce of 9 plots with artificial mineral manures - - -	17 3½	1096	1240
Superphosphate of lime 350 lbs. -			
Phosphate of Magnesia 168 lbs. -			
do potass 150 lbs. -			
Silicate do. 112 lbs. -	16 3½	1009	1155
Mean of the 9 plots with artificial mineral manures - - -			
Mean of 3 plots with mineral manures, and 65 lbs. each of sulphate of ammonia - -	21 0	1275	1423
Mean of 2 plots with mineral manures, and 150 lbs. and 160 lbs. of rape-cake respectively	18 1½	1078	1201
Plot 18. With complex mineral manure, 55 lbs. of sulphate of ammonia, and 150 lbs. of rape-cake	22 8½	1368	1768

"The indications of the table are seen to be most conclusive, as showing what was the character of the exhaustion which had been induced by the previous heavy cropping, and what, therefore, should be the peculiar nature of the supply in a rational system of manuring. If the exhaustion had been connected with a deficiency of mineral constituents, we might reasonably have expected that by some one at least of the nine mineral conditions,—supposing in some cases an abundance of every mineral constituent which the plant could require,—this deficiency would have been made up; but it was not so.

"Thus, taking the column of bushels per acre as given in this summary as our guide, it will be seen that whilst we have without manure only 16 bushels of dressed corn, we

have by farm-yard manure 22 bushels. The *ashes*, of farm-yard manure give, however, no increase whatever over the unmanured plot. Again, out of the 9 plots supplied with artificial mineral manures, we have in no case an increase of 2 bushels by this means; the produce of the average of the 9 being not quite 17 bushels. On the other hand we see that these addition to some of the purely mineral manures of 65 lbs. of sulphate of ammonia—a very small dressing of that substance, and containing only about 14 lbs of ammonia—has given us an average produce of 21 bushels. An insignificant addition of rape-cake too, to manures otherwise ineffective, has given us about 18½ bushels; and when, as in plot 18., we have added to the inefficient mineral manures 65 lbs. of ammoniacal salts, and a little rape-cake also, we have a produce greater than by the 14 tons of farm-yard manure.

"The quantities of rape-cake used were small, and the increase attributable to it also small, but it nevertheless was much what we should expect when compared with that from the ammoniacal salts, if, as we believe is the case, the effect of rape-cake on *grain-crops* is due to the nitrogen it contains.

"Indeed, the coincidence in the slight or non-effect throughout the mineral series on the one hand, and of the marked and nearly uniform result of the nitrogenous supply on the other, was most striking in the first year's experimental produce, and such as to lead us to give to nitrogenous manures in the second season even greater prominence than we had done to minerals in the previous one. This is in some respects, perhaps, to be regretted, as had we kept a series of plots for some years continuously under minerals alone, the evidence, though at present sufficiently conclusive, would have carried with it somewhat more of *systematic* proof.

"In Table II. we have given a few results selected from those obtained at the harvest of 1845, the second of the experimental series. By the table it is seen that we have, at the harvest of 1845, a produce of rather more than 23 bushels without manure of any kind, instead of only 16 as in 1844; and in like manner the farm-yard manure gives 32 bushels in 1845, and only 22 in 1844. We have shown in a former number of the Journal how clearly these differences can be traced to variations in the climatic character of the *season*, but this is not the point under consideration just now.

TABLE II.—Harvest 1845. Selected results.

Description and Quantities of the Manures per Acre.		Dressed Corn per Acre in Bushels and Pecks.		Total Corn per Acre, in lbs.	Straw per Acre, in lbs.
		bush.	pecks.	lbs.	lbs.
Section 1.					
Plot 3. No manure		23	0½	1441	2712
" 2. 14 tons of farm-yard manure		32	0½	1967	3915
Section 2.					
" 5a. No manure		22	2½	1431	2684
" 5b. Top-dressed with 252 lbs. of carbonate of ammonia (dissolved), at 3 times, during the spring		26	3½	1732	3599
Section 3.					
" 9. { Sulphate of ammonia 168 lbs. } top-dress'd		33	1½	2131	4058
" { Muriate of ammonia 168 lbs. } at once					
" 10. { Sulphate of ammonia 168 lbs. } top-dress'd		31	3½	1980	4266
" { Muriate of ammonia 168 lbs. } at 4 times.					

"We assume, then, 23 bushels or thereabouts to be the standard produce of the soil and season, without manure, during this second experimental year; and as part of plot 5. (previously manured with superphosphate of lime), and which is now, also, without manure, gives rather more than 22½ bushels of dressed corn, the correctness of the result of plot 3., the permanently unmanured plot, is thereby fully confirmed.

"This plot No. 5., previously two-thirds of an acre, was, in this second year, divided into two equal portions; one of these ('plot 5a') being, as just said, unmanured, and the other ('plot 5b') having supplied to it in solution, by top-dressings during the spring, the medicinal carbonate of ammonia, at the rate of 250 lbs. per acre; and it is seen that we have, by this pure but highly volatile ammoniacal salt alone, the produce raised from 22½ bushels to very nearly 27 bushels!

"In the next section of the table are given the results of plots 9. and 10., the former of

which had in the previous year been manured by superphosphate of lime and a small quantity of sulphate of ammonia, and the latter by superphosphate of lime and silicate of potass. To each of the plots $1\frac{1}{2}$ cwt. of sulphate and $1\frac{1}{2}$ cwt. of muriate of ammonia were now supplied. Upon plot 9. the whole of the manure was top-dressed, at once, early in the spring; but on plot 10. the salts were put on at four successive periods. The produce obtained by these salts of ammonia alone is 33 bushels and three-eighths, when sown all at once, and nearly 32 bushels when sown at four different times—quantities which amount to about 10 bushels per acre more than was obtained without manure. In the case of No. 9, indeed, the produce exceeds by $1\frac{1}{4}$ bushel that given by farm-yard manure, and in that of No. 10. it is all but identical with it. And if we take the weights of total corn, instead of the *measure* of the dressed corn, to which latter we chiefly refer, merely as a standard more conventionally understood, No. 10., by ammonia only, has given both more corn and more straw than the farm-yard manure, with all its minerals and carbonaceous substance.

"Let us see whether this almost specific effect of nitrogen, in restoring, for the reproduction of corn, a corn-exhausted soil, is borne out by the results of succeeding years.

"We should have omitted all reference to the results obtained with the wheat manure of Professor Liebig, had not the professor, in the new edition of his 'Letters,' whilst fully admitting the failure of the manure—the composition of which, to use his own words when commenting upon it, 'could be no secret, since every plant showed by its ashes the due proportion of the constituents essential to its growth' (page 482),—not expressed any doubt as to the principle involved in such a manure, but on the other hand, implied that the failure was due to a yet imperfect knowledge of the mechanical form and chemical qualities required to be given to the necessary constituents in order to fit them for their reception and nutritive action on the plant, rather than to any fallacy in the theory which would recommend to practical agriculture the supply by artificial means of the constituents of the ashes of plants as manures.

"The following table gives our selection of the results of the third season, 1846:—

TABLE III.—Harvest 1846. Selected Results.

Description and Quantities of the Manures per Acre.	Dressed Corn per Acre, in Bushels and Pecks.		Total Corn per acre, in lbs.	Straw per Acre, in lbs.
	bush.	pecks.	lbs.	lbs.
Section 1.				
Plot 3. No manure	17	$3\frac{1}{4}$	1207	1513
" 2. 14 tons of farm-yard manure	27	$0\frac{1}{4}$	1826	2454
Section 2.				
" 10b. No manure	17	$2\frac{1}{4}$	1216	1455
" 10a. Sulphate of ammonia 224 lbs.	27	$1\frac{1}{4}$	1850	2244
Section 3.				
" 5a ¹ . Ash of 3 loads of wheat straw	19	$0\frac{1}{4}$	—	1541
" 5a ² . Ash of 3 loads of wheat straw, and top-dressed with 224 lbs. of sulphate of ammonia	27	0	—	2309
Section 4.				
" 6a. Liebig's wheat manure 448 lbs.	20	$1\frac{1}{2}$	1400	1676
" 6b. Liebig's wheat manure 448 lbs., with 112 lbs. each of sulphate and muriate of ammonia	29	$0\frac{1}{4}$	1967	2571

"At this third experimental harvest we have on the continuously unmanured plot, namely, No. 3., not quite 18 bushels of dressed corn, as the normal produce of the season; and by its side we have on plot 10b.—comprising one-half of the plot 10. of the previous years, and so highly manured by ammoniacal salts in 1845, but now unmanured,—rather more than $17\frac{1}{4}$ bushels. The near approach, again, to identity of result from the two unmanured plots, at once gives confidence in the accuracy of the experiments, and shows us how effectually the preceding crop had, in a practical point of view, reduced the plots, previously so differently circumstanced both as to manure and produce, to something like an uniform standard as regards

their grain-producing qualities. We take this opportunity of particularly calling attention to these coincidences in the amount of produce in the two unmanured plots of the different years, because it has been objected against our experiments, as already published, that confirmation was wanting as to the natural yield of soil and season.

"Plot 2 has, as before, 14 tons of farm-yard manure, and the produce is $27\frac{1}{2}$ bushels, or between 9 and 10 bushels more than without manure of any kind.

"On plot 10a, which in the previous year gave by ammoniacal salts alone a produce equal to that of the farm-yard manure, we have again a similar result: for 2 cwt. of sulphate of ammonia has now given 1850 lbs. of total corn, instead of 1826 lbs., which is the produce on plot 2. The straw of the latter is, however, slightly heavier than that by the ammoniacal salt.

"Again, plot 5a, which was in the previous season *unmanured*, was now subdivided: on one-half of it (namely, 5a') we have the ashes of wheat-straw alone, by which there is an increase of rather more than 1 bushel per acre of dressed corn; on the other half (or 5a'') we have, besides the straw ashes, 2 cwt. of sulphate of ammonia put on as a top-dressing: 2 cwt. of sulphate of ammonia have, in this case, only increased the produce beyond that of 5a' by $7\frac{1}{2}$ bushels of corn and 768 lbs. of straw, instead of by $9\frac{1}{2}$ bushels of corn and 789 lbs. of straw, which was the increase obtained by the same amount of ammoniacal salt on 10a, as compared with 10b. It will be observed, however, that in the former case the ammoniacal salts were top-dressed, but in the latter they were drilled at the time of sowing the seed; and it will be remembered that in 1845 the result was better *as to corn* on plot 9, where the salts were sown earlier, than on plot 10, where the top-dressing extended far into the spring. We have had several direct instances of this kind in our experience, and we would give it as a suggestion, in most cases applicable, that manures for wheat, and especially ammoniacal ones, should be applied before or at the time the seed is sown; for although the apparent luxuriance of the crop is greater, and the produce of straw really heavier, by spring rather than autumn sowings of Peruvian guano and other ammoniacal manures, yet we believe that that of the *corn* will not be increased in an equivalent degree. Indeed, the success of the crop undoubtedly depends very materially on the progress of the underground growth during the winter months; and this again, other things being equal, upon the quantity of available nitrogenous constituents within the soil, without a liberal provision of which, the range of the fibrous feeders of the plant will not be such as to take up the minerals which the soil is competent to supply, and in such quantity as will be required during the after progress of the plant for its healthy and favorable growth.

"The next result to be noticed is that obtained on plot 6, now also divided into two equal portions, designated respectively 6a and 6b. Plot No. 6 had for the crop of 1844 superphosphate of lime and the phosphate of magnesia manure, and for that of 1845 superphosphate of lime, rape-cake, and ammoniacal salts. For this the third experimental season, it was devoted to the trial of the wheat manure manufactured under the sanction of Professor Liebig, and patented in this country.

"Upon plot 6a 4 cwt. per acre of the patent wheat-manure were used, which gave $20\frac{1}{2}$ bushels, or rather more than 2 bushels beyond the produce of the unmanured plot; but as the manure contained, besides the minerals peculiar to it, some nitrogenous compounds, giving off a very perceptible odor of ammonia, some, at least, of the increase would be due to that substance. On plot 6b, however, the further addition of 1 cwt. each of sulphate and muriate of ammonia to this so-called "mineral manure" gives a produce of $29\frac{1}{2}$ bushels. In other words, the addition of ammoniacal salt to Liebig's mineral manure has increased the produce by very nearly 9 bushels per acre beyond that of the mineral manure alone, whilst the increase obtained over the unmanured plot, by 14 tons of farm-yard manure, was only $9\frac{1}{2}$ bushels.

"If, then, the 'mechanical form and chemical qualities' of the so-called 'mineral manure' were at fault, the sulphate of ammonia has, at least, compensated for the defect; and even supposing a mineral manure, founded on a knowledge of the composition of the ashes of the plant, be still the great desideratum, the farmer may rest contented, meanwhile, that he has in ammonia, supplied to him by Peruvian guano, by ammoniacal salts, and by other sources, so good a substitute.

"It surely is needless to attempt further to justify, by the results of individual years, our assertion, that in practical agriculture nitrogenous manures are peculiarly adapted to the growth of wheat. We shall therefore conclude this part of our subject by directing attention to the history of a few of the plots throughout the entire series of years, as compared with that of the unmanured plot during the same period.

"In support of the view that leguminous plants do possess a superior power of reliance upon the atmosphere for their nitrogen, and, indeed, that it is to this property that they materially owe their efficacy in rotation with grain, we may refer to the admirable investigations into the chemistry of agriculture of M. Boussingault. His experiments, however, have not received the attention which they merit from the

agriculturists of this country; probably on account of the small amounts of produce which he obtained. But it must be remembered that his investigation had for its object to explain the practices of agriculture as he found them in his own locality, before attempting to deviate from its established rules. M. Boussingault states the rotation usually adopted at Bechelbronn, and throughout the greater part of Alsace, to be as follows:—

"Potatoes or beet-root;" "Wheat;" "Clover;" "Wheat;"

and that the average of wheat so obtained is, after potatoes 19½ bushels, after beet-root 17 bushels, after clover 24 bushels. Now we find by reference to his table that the first crop of wheat, grain, and straw removed 17 lbs. of phosphoric acid and 24 lbs. of potash and soda; the following clover crop, 18 lbs. of phosphoric acid and 77 lbs. potash and soda; and after this removal of alkalis and phosphates by the clover a larger crop of wheat is obtained. Surely it would seem impossible to reconcile this result with a theory which supposes the produce of wheat to rise and fall with the quantity of minerals available within the soil. If, however, we admit that the first crop of wheat could not take up the mineral matters existing in the soil for want of nitrogenous supply, and that the clover crop, not being so dependent upon supplied nitrogen, was able to take up the minerals required for its growth, and that it moreover left in the soil sufficient ammonia, or its equivalent of nitrogen in some form, to give the increased crop of wheat, we have a much more consistent and probable solution of the results. There is little doubt that M. Boussingault could have increased his produce of wheat by means of ammoniacal salts: whether he could have done so economically is another question, depending of course upon the relative prices of grain and ammonia.

"The striking effect of phosphoric acid upon the growth of the turnip, indeed, is a fact so well known to every intelligent agriculturist in Great Britain, that it would seem quite superfluous to attempt to illustrate it by any direct experiments of our own. However, as Professor Liebig has again, in the recent edition of his 'Letters,' expressed an opinion entirely inconsistent with such a result, we will refer to one or two of the results obtained in our experimental turnip-field, which bear upon the opinion he has reiterated as follows: thus, speaking of the exhaustion of phosphate of lime and alkaline phosphates by the sale of flour, cattle, &c., he says:—'It is certain that this incessant removal of the phosphates must tend to exhaust the land and diminish its capability of producing grain. The fields of Great Britain are in a state of progressive exhaustion from this cause, as is proved by the rapid extension of the cultivation of turnips and mangold-wurzel, plants which contain the least amount of the phosphates, and THEREFORE REQUIRE THE SMALLEST QUANTITY FOR THEIR DEVELOPMENT.' Now we do not hesitate to say that, however small the quantity of phosphates contained in the turnip, the successful cultivation of it is more dependent upon a large supply of phosphoric acid in the manure than that of any other crop.

"In the following table, then, is given the amounts of bulb, since 1843, of—

First, the continuously unmanured plot;

Secondly, that with a large amount of the superphosphate of lime alone each year; and

Thirdly, that with a very liberal supply of potash with some soda and magnesia also, in addition to superphosphate of lime.

Years.	Plot continuously Unmanured.				Plot with Superphosphate of Lime alone every Year.				Plot with Superphosphate of Lime and mixed Alkalis.

"It is seen then, that in the third season, viz. 1845, the produce of the unmanured plot is reduced to a few hundred weights, and since that period the size of the bulbs had been such that they have not been considered worth weighing. On the other hand, on the plot with superphosphate of lime alone for eight successive years, we have an average produce of about 8½ tons of bulb! varying, however, exceedingly, year by year, accord-

ing to the season. We see, too, that by the addition to superphosphate of lime of a large quantity of the alkalis, much greater than could be taken off in the crop, the average produce is not so great by nearly half a ton as by the superphosphate of lime alone. It must be admitted that this extraordinary effect of superphosphate of lime cannot be accounted for by the idea of merely supplying in it the actual constituents of the crop, but that it is due to some special agency in developing the assimilative processes of the plant. This opinion is favored by the fact that in the case where the superphosphate of lime is at once neutralized by alkalis artificially supplied, the efficiency of the manure would seem to be thereby reduced. And from this again, we would gather that the effect of the phosphoric acid, as such, cannot be due merely to the liberation within the soil of its alkalis, or we should suppose that the artificial supply of these would at least have been attended with some increase of produce. But this is not the case, notwithstanding that by means of superphosphate of lime alone there has been taken from the land more of the alkalis in which the ash of the turnip so peculiarly abounds, than would have been lost from it in a century under the ordinary course of rotation and home manuring! Collateral experiments also clearly prove the importance of a liberal supply of organic substance rich in carbon—which always contains a considerable quantity of nitrogen also—if we would in practical agriculture increase the yield much beyond the amount which can be obtained by mineral manures alone; and these conditions being fulfilled, the direct supply of nitrogen, on the other hand, is by no means so generally essential. And it is where we have provided a liberal supply of constituents for organic formations, in addition to the mineral manures, that we have found the use of alkalis not to be without effect.

"But it is at any rate certain that phosphoric acid, though it forms so small a proportion of the ash of the turnip, has a very striking effect on its growth when applied as manure; and it is equally certain that the extended cultivation of root crops in Great Britain cannot be due to the deficiency of this substance for the growth of corn, and to the less dependence upon it of the root crops, as supposed by Baron Liebig.

"These curious and interesting facts in relation to the growth of turnips, as well as those which have been given in reference to wheat and to the leguminous crops, are sufficient to prove how impossible it is to form correct opinions on agricultural chemistry without the guidance of direct experiment in the field. And we are convinced that if Baron Liebig had watched the experiments which we have had in progress during the last eight years, he would long ago have arrived at conclusions in the main agreeing with those to which we have been irresistibly led: and we are disposed to believe that had he even seen the more detailed accounts of our results given in our own papers in this Journal, instead of the mere reference to them made by Mr. Pusey, he would rather have accepted them, as a step in an inquiry to which his own researches and writings had given such an impetus, than have designated them, as he has done, as entirely without value.

"So much, then, for the results of experiments in the field, and for the considerations in relation to the functional actions of plants, as bearing upon the character of the manure required for their growth in a course of practical agriculture. Let us now consider for a few moments what really are the main and characteristic features of practical agriculture, as most generally followed in this country.

"Let us suppose that the rotation adopted is that of turnips, barley, clover, wheat; that the turnips and clover are consumed upon the farm by stock, and that the meat thus produced, 40 bushels of barley and 30 bushels of wheat, are all the exports from the farm, the manure from the consumed turnips and clover, and the straw, both of barley and of wheat being retained upon the farm. We have in this case, by the sale of grain, a loss of minerals to each acre of the farm of only 20 to 24 pounds of potash and soda, and 26 to 30 pounds of phosphoric acid, in the course of the rotation, or an average of 5 to 6 lbs. of potash and soda, and $6\frac{1}{2}$ to $7\frac{1}{2}$ lbs of phosphoric acid per acre per annum. In the sale of the animals there would of course be an additional loss of phosphoric acid, though, especially if no breeding stock were kept, this would be even much less considerable than in that of the grain; and the amount of the alkalis thus sent off the farm would, according to direct experiments of our own upon calves, bullocks, lambs, sheep, and pigs, probably be only about one-fourth that of the phosphoric acid. It has, however, long been decided in practical agriculture that phosphoric acid may be advantageously provided in the purchase of bones or other phosphatic manures, though in practice these are not found applicable as a direct manure for the wheat crop; and as we have already said, even when employed for the turnip, its efficacy is not to be accounted for merely as supplying a sufficiency of that substance to be stored up in the crop.

"In conclusion, then: if the theory of Baron Liebig simply implies that the growing plant must have within its reach a sufficiency of the mineral constituents of which it is to be built up, we fully and entirely assent to so evident a truism; but if, on the other hand, he would have it understood that it is of the mineral constituents, as would be collectively found in the ashes of the exported produce, that our soils are deficient relatively to other constituents, and that, in the present condition of agriculture in Great

Britain, 'we cannot increase the fertility of our fields by a supply of nitrogenized products, or by salts of ammonia alone, but rather that their produce increases or diminishes, in a direct ratio, with the supply of mineral elements capable of assimilation,' we do not hesitate to say that every fact with which we are acquainted, in relation to this point, is unfavorable to such a view. We have before stated, that if a *cheap* source of ammonia were at command, the available mineral constituents might in their turn become exhausted by its excessive use.

"NOTE.—This important paper so completely establishes what I wrote in our last Number on the entire failure of the mineral theory as a guide to the use of manures in practical farming, that I need only express my regret for the annoyance which its author has publicly expressed, as I am told, at those remarks. In cautioning the English farmer against what seemed to me a dangerous error, I certainly endeavored to do justice to the real discoveries of Baron Liebig. Since the experiments, however, of Mr. Lawes and Dr. Gilbert have, as I hear, been disputed, I am bound to say that my confidence in the scrupulous accuracy of those gentlemen has been only strengthened by a subsequent visit to Rothamsted, in company with that eminent philosopher, Mons. Dumas. The extent of the experimental ground—the expenditure at which it has been kept up—the perseverance with which, year after year, it has been maintained, are such as might rather be expected from a public institution than a private landowner, and render Rothamsted, at present, the principal source of trustworthy scientific information on agricultural Chemistry."—*Ph. Pusey.*

MANURE MANUFACTURE. The fecal matter so abundantly collected and dried in Paris, to form their dry portable manure, called *poudrette*, is now mixed in its preparation with a small portion of a solution of sulphate of iron (*copperas*), whereby it loses its offensive smell, and may be evaporated without causing a nuisance to the neighborhood. The ammonia, as well as the sulphuretted and phosphuretted hydrogen, which together concur to produce the nauseous effluvia, are at once condensed by this salt; the ammonia by its acid, and the gases by its oxide. When the putrid contents of a cesspool are mixed with a little copperas, they soon become nearly inodorous. This cheap metallic compound should be applied, under the administration of the police, to all the masses of putrefying dung which are deposited in the parlious of London, and of the other large towns in the United Kingdom.

Estimated Quantities of Peruvian Guano.

The importations of Peruvian guano into Great Britain, according to the Parliamentary Returns, have been,—

1846	22,410 tons	1849	78,567 tons
1848	57,762	1850	95,083
1848	61,055	1851	199,732

showing an enormous progressive increase.

MARBLE. This title embraces such of the primitive, transition, and purer compact limestones of secondary formation, as may be quarried in solid blocks without fissures, and are susceptible of a fine polished surface. The finer the white, or more beautifully variegated the colors of the stone, the more valuable, *ceteris paribus*, is the marble. Its general characters are the following:—

Marble effervesces with acids; affords quicklime by calcination; has a conchoidal scaly fracture; is translucent only on the very edges; is easily scratched by the knife; has a spec. grav. of 2.7; admits of being sawn into slabs, and receives a brilliant polish. These qualities occur united in only three principal varieties of limestone; in the saccharoid limestone, so called from its fine granular texture resembling that of loaf sugar, and which constitutes modern statuary marble, like that of Carrara; 2. in the foliated limestone, consisting of a multitude of small facets formed of little plates applied to one another in every possible direction, constituting the antique statuary marble, like that of

Paros; 3. in many of the transition and carboniferous, or *enerinitic* limestones, subordinate to the coal formation.

The saccharoid and lamellar, or statuary marbles, belong entirely to primitive and transition districts. The greater part of the close-grained colored marbles belong also to the same geological localities; and become so rare in the secondary limestone formations, that immense tracts of these occur without a single bed sufficiently entire and compact to constitute a workable marble. The limestone lying between the calcareo-silicious sands and gritstone of the under oolite, and which is called Forest marble in England, being susceptible of a tolerable polish, and variegated with imbedded shells, has sometimes been worked into ornamental slabs in Oxfordshire, where it occurs in the neighborhood of Whichwood forest; but this case can hardly be considered as an exception to the general rule. To constitute a profitable marble-quarry, there must be a large extent of homogeneous limestone, and a facility of transporting the blocks after they are dug. On examining these natural advantages of the beds of Carrara marble, we may readily understand how the statuary marbles discovered in the Pyrenees, Savoy, Corsica, &c. have never been able to come into competition with it in the market. In fact, the two sides of the valley of Carrara may be regarded as mountains of statuary marble of the finest quality.

Gypseous alabaster may be readily distinguished from marbles, because it does not effervesce with acids, and is soft enough to be scratched by the nail; stalagmitic alabaster is somewhat harder than marble, translucent, and variegated with regular stripes or undulations.

Some granular marbles are flexible in thin slabs, or, at least, become so by being dried at the fire; which shows, as Dolomieu suspected, that this property arises from a diminution of the attractive force among the particles, by the loss of the moisture.

The various tints of ornamental marbles generally proceed from oxides of iron; but the blue and green tints are sometimes caused by minute particles of hornblende, as in the slate-blue variety called Turchino, and in some green marbles of Germany. The black marbles are colored by charcoal, mixed occasionally with sulphur and bitumen; when they constitute stinkstone.

Brard divides marbles, according to their localities, into classes, each of which contains eight subdivisions:—

1. Uni-colored marbles; including only the white and the black.
2. Variegated marbles; those with irregular spots or veins.
3. Madreporic marbles, presenting animal remains in the shape of white or gray spots, with regularly disposed dots and stars in the centre.
4. Shell marbles; with only a few shells interspersed in the calcareous base.
5. Lumachella marbles, entirely composed of shells.
6. Cipollin marbles, containing veins of greenish tale.
7. Breccia marbles, formed of a number of angular fragments of different marbles, united by a common cement.
8. Puddingstone marbles; a conglomerate of rounded pieces.

Antique marbles.—The most remarkable of these are the following:—*Parian marble*, called *lychnites* by the ancients, because its quarries were worked by lamps; it has a yellowish-white color; and a texture composed of fine shining scales, lying in all directions. The celebrated Arundelian tables at Oxford consist of Parian marble, as well as the Medicean Venus. *Pentelic marble*, from Mount Penteles, near Athens, resembles the Parian, but is somewhat denser and finer grained, with occasional greenish zones, produced by greenish tale, whence it is called by the Italians *Cipolino statuario*. The Parthenon, Propyleum, the Hippodrome, and other principal monuments of Athens, were of Pentelic marble; of which fine specimens may be seen among the Elgin collection, in the British Museum. *Marmo Greco*, or Greek white marble, is of a very lively snow white color, rather harder than the preceding, and susceptible of a very fine polish. It was obtained from several islands of the Archipelago, as Scio, Samos, Lesbos, &c. *Translucent white marble*, *Marmo statuario* of the Italians, is very much like the Parian, only not so opaque. Columns and altars of this marble exist in Venice, and several towns of Lombardy; but the quarries are quite unknown. *Flexible white marble*, of which five or six tables are preserved in the house of Prince Borghese, at Rome. The *white marble of Luni*, on the coast of Tuscany, was preferred by the Greek sculptors to both the Parian and Pentelic. *White marble of Carrara*, between Specia and Lucca, is of a fine white color, but often traversed by gray veins, so that it is difficult to procure moderately large pieces free from them. It is not so apt to turn yellow as the Parian marble. This quarry was worked by the ancients, having been opened in the time of Julius Cæsar. Many antique statues remain of this marble. Its two principal quarries at the present day are those of Pianello and Polvazzo. In the centre of its blocks very limpid rock-crystals are sometimes found, which are called Carrara diamonds. As the finest qualities are becoming excessively rare, it has risen in price to about 3 guineas the

cubic foot. The *White marble* of Mount Hymettus, in Greece, was not of a very pure white, but inclined a little to gray. The statue of Meleager, in the French Museum, is of this marble.

Black antique marble, the *Nero antico* of the Italians. This is more intensely black than any of our modern marbles; it is extremely scarce, occurring only in sculptured pieces. The *red antique marble*, *Egyptum* of the ancients, and *Rosso antico* of the Italians, is a beautiful marble of a deep blood-red color, interspersed with white veins and with very minute white dots, as if strewn over with grains of sand. There is in the Grimani palace at Venice, a colossal statue of Marcus Agrippa in *rosso antico*, which was formerly preserved in the Pantheon at Rome. *Green antique marble*, *verde antico*, is a kind of breccia, whose paste is a mixture of talc and limestone, while the dark green fragments consist of serpentine. Very beautiful specimens of it are preserved at Parma. The best quality has a grass-green paste, with black spots of noble serpentine, but is never mingled with red spots. *Red spotted green antique marble*, has a dark green ground marked with small red and black spots, with fragments of *entrochi* changed into white marble. It is known only in small tablets. *Leck marble*; a rare variety of that color, of which there is a table in the Mint at Paris. *Marmo verde pagliocco* is of a yellowish green color, and is found only in the ruins of ancient Rome. *Cereolas marble* of a deep red, with numerous gray and white veins, is said to be found in Africa, and highly esteemed in commerce. *Yellow antique marble*, *giallo antico* of the Italians; color of the yolk of an egg, either uniform or marked with black or deep yellow rings. It is rare, but may be replaced by Sienna marble. *Red and white antique marbles*, found only among the ruins of ancient Rome. *Grand antique*, a breccia marble, containing shells, consists of large fragments of a black marble, traversed by veins or lines of a shining white. There are four columns of it in the Museum at Paris. *Antique Cipolino marble*. Cipolin is a name given to all such marbles as have greenish zones produced by green talc; their fracture is granular and shining, and displays here and there plates of talc. *Purple antique breccia marble*, is very variable in the color and size of its spots. *Antique African breccia* has a black ground, variegated with large fragments of a grayish-white, deep red, or purplish wine color; and is one of the most beautiful marbles. *Rose-colored antique breccia marble* is very scarce, occurring only in small tablets. There are various other kinds of ancient breccias, which it would be tedious to particularize.

Modern marbles.—1. *British*. Black marble is found at Ashford, Matlock, and Monsaldale in Derbyshire; black and white in the north part of Devonshire; the variegated marbles of Devonshire are generally reddish, brownish, and grayish, variously veined with white and yellow, or the colors are often intimately blended; the marbles from Torbay and Babbacombe, display a great variety in the mixture of their colors; the Plymouth marble is either ash-colored with black veins, or blackish-gray and white, shaded with black veins; the cliffs near Marychurch exhibit marble quarries not only of great extent, but of superior beauty to any other in Devonshire, being either of a dove-colored ground with reddish-purple and yellow veins, or of a black ground mottled with purplish globules. The green marble of Anglesea is not unlike the *verde antico*; its colors being greenish-black, leek-green, and sometimes dull purplish, irregularly blended with white. The white part is limestone, the green shades proceed from serpentine and asbestos. There are several fine varieties of marble in Derbyshire; the mottled-gray in the neighborhood of Moneyash, the light gray being rendered extremely beautiful by the number of purple veins which spread upon its polished surface in elegant irregular branches; but its chief ornament is the multitude of *entrochi*, with which this transition limestone-marble abounds. Much of the transition and carboniferous limestone of Wales and Westmoreland is capable of being worked up into agreeable dark marbles.

In Scotland, a particularly fine variety of white marble is found in immense beds, at Assynt in Sutherlandshire. A beautiful ash-gray marble of a very uniform grain, and susceptible of a fine polish, occurs on the north side of the ferry of Ballachulish in Invernesshire. One of the most beautiful varieties is that from the hill of Belepethrich in Tiree, one of the Hebrides. Its colors are pale blood-red, light flesh-red, and reddish-white, with dark green particles of hornblende, or rather sahite, diffused through the general base. The compact marble of Iona is of a fine grain, a dull white color, somewhat resembling pure compact feldspar. It is said by Bournon, to consist of an intimate mixture of tremolite and carbonate of lime, sometimes with yellowish or greenish-yellow spots. The carboniferous limestone of many of the coal basins in the lowlands of Scotland may be worked into a tolerably good marble for chimney-pieces.

In Ireland, the Kilkenny marble is the one best known, having a black ground more or less varied with white marks produced by petrifications. The spar which occupies the place of the shells, sometimes assumes a greenish-yellow color. An exceedingly fine black marble has also been raised at Crayleath in the county of Down. At Louthlougher, in the county of Tipperary, a fine purple marble is found, which when polished looks

very beautiful. The county of Kerry affords several variegated marbles, not unlike the Kilkenny.

France possesses a great many marble quarries which have been described by Brard, and of which a copious abstract is given under the article marble—*Rees' Cyclopaedia*.

The territory of Genoa furnishes several beautiful varieties of marble, the most remarkable of which is the *polzevera di Genoa*, called in French the *vert d'Egypte* and *vert de mer*. It is a mixture of granular limestone with a talcose and serpentine substance disposed in veins; and it is sometimes mixed with a reddish body. This marble was formerly much employed in Italy, France, and England, for chimney-pieces, but its sombre appearance has put it out of fashion.

Corsica possesses a good statuary marble of a fine close grain, and pure milky whiteness, quarried at Ornofrio; it will bear comparison with that of Carrara; also a gray marble (*bardiglio*), a cipolin, and some other varieties. The island of Elba has immense quarries of a white marble with blackish-green veins.

Among the innumerable varieties of Italian marbles, the following deserve especial notice.

The *roviglio*, a white marble found at Padua; the white marble of St. Julien, at Pisa, of which the cathedral and celebrated slanting tower are built; the Biancone marble, white with a tinge of gray, quarried at Magurega for altars and tombs. Near Mergozza the white saline marble with gray veins is found; with which the cathedral of Milan is built. The black marble of Bergamo is called *paragone*, from its black color, like touchstone; it has a pure intense tint, and is susceptible of a fine polish. The pure black marble of Como is also much esteemed. The *polveroso* of Pistoia, is a black marble sprinkled with dots; and the beautiful white marble with black spots, from the Lago Maggiore, has been employed for decorating the interior of many churches in the Milanese. The Margorze marble found in several parts of the Milanese, is bluish veined with brown, and composes part of the dome of the cathedral of Milan. The green marble of Florence owes its color to a copious admixture of steatite. Another green marble, called *verde di Prado*, occurs in Tuscany, near the little town of Prado. It is marked with spots of a deeper green than the rest, passing even into blackish-blue. The beautiful Sienna marble, or *brocattello di Siena*, has a yellow color like the yolk of an egg, which is disposed in large irregular spots, surrounded with veins of bluish-red, passing sometimes into purple. At Montarenti, two leagues from Sienna, another yellow marble is met with, which is traversed by black and purplish-black veins. The Brema marble is yellow with white spots. The *mandelato* of the Italians is a light red marble with yellowish-white spots, found at Luggezzana, in the Veronese. The red marble of Verona is of a red rather inclining to yellow or hyacinth; a second variety of a dark red, composes the vast amphitheatre of Verona. Another marble is found near Verona, with large white spots in a reddish and greenish paste. Very fine columns have been made of it. The *occhio di pavone* is an Italian shell marble, in which the shells form large orbicular spots, red, white, and bluish. A madreporic marble known under the name of *pietra stellaria*, much employed in Italy, is entirely composed of star madrepores, converted into a gray and white substance, and is susceptible of an excellent polish. The village of Bretonico, in the Veronese, furnishes a splendid breccia marble, composed of yellow, steel-gray, and rose-colored spots. That of Bergamo consists of black and gray fragments in a greenish cement. Florence marble, called also ruin and landscape marble, is an indurated calcareous marl.

Sicily abounds in marbles, the most valuable of which is that called by the English stone-cutters, Sicilian jasper; it is red with large stripes like ribbands, white, red, and sometimes green, which run zigzag with pretty acute angles.

Among the Genoese marbles we may notice the highly esteemed variety called *portor*, on account of the brilliant yellow veins in a deep black ground. The most beautiful kind comes from Porto-Venese, and Louis XIV. caused a great deal of it to be worked up for the decoration of Versailles. It costs now two pounds per cubic foot.

Of cutting and polishing marble.—The marble saw is a thin plate of soft iron, continually supplied during its sawing motion, with water and the sharpest sand. The sawing of moderate pieces is performed by hand, but that of large slabs is most economically done by a proper mill.

The first substance used in the polishing process is the sharpest sand, which must be worked with till the surface becomes perfectly flat. Then a second, and even a third sand of increasing fineness is to be applied. The next substance is emery of progressive degrees of fineness, after which tripoli is employed; and the last polish is given with tin-putty. The body with which the sand is rubbed upon the marble, is usually a plate of iron; but for the subsequent process, a plate of lead is used with fine sand and emery. The polishing rubbers are coarse linen cloths, or bagging, wedged tight into an iron planing tool. In every step of the operation, a constant trickling supply of water is required.

Visitors of Derby may have an opportunity of inspecting Brown's extensive machinery for cutting marble into many ornamental forms, which has been well described in *Rees's Cyclopaedia*.

Sir James Jelf patented, in 1822, a combination of machinery for cutting any description of parallel mouldings upon marble slabs, for ornamental purposes; in which tools, supplied with sand and water, are made to traverse to and fro.

Mr. Tullock obtained a patent, in 1824, for improvements in machinery for sawing and grooving marble; the power being applied by means of toothed wheels bearing cranks, which gave the sea-saw motion to the cutting iron plates.

In November, 1829, Mr. Gibbs secured, by patent, an invention for working ornamental devices in marble, by means of a travelling drill, guided by a mould of wood, &c., in counter relief; and in April, 1833, Mr. G. W. Wilds obtained a patent for machinery, which consists of a series of circular cutters, for separating slabs from a block of marble; the block being advanced slowly to meet the cutters, by the progressive movement of a platform upon wheels, driven by the agency of a rack and pinion, as in the cylinder boring machine of the steam-engine manufacturer. Sand and water must be supplied, of course, from a hopper, to these smooth-cutting discs of iron or copper. See GLASS-CUTTING. He proposes also to mould and polish marble, by applying a rotatory wheel or cylinder of any shape to it, in its carrying frame.

MARCASITE, is a variety of iron pyrites, containing generally a little arsenic.

MARGARATES, are saline compounds of margaric acid with the bases.

MARGARIC ACID, is one of the acid fats, produced by saponifying tallow with alkaline matter, and decomposing the soap with dilute acid. The term Margaric signifies PEARLY-looking.

The physical properties of the margaric and stearic acids are very similar; the chief difference is that the former is more fusible, melting at 140° F. The readiest mode of obtaining pure margaric acid, is to dissolve olive oil soap in water, to pour into the solution a solution of neutral acetate of lead, to wash and dry the precipitate, and then to remove its oleate of lead by ether, which does not affect its margarate of lead. The residuum being decomposed by boiling hot muriatic acid, affords margaric acid. When heated in a retort this acid boils. It is insoluble in water, very soluble in alcohol and ether; it reddens litmus paper, and decomposes, with the aid of heat, the carbonates of soda and potash.

MARGARIC ACID is obtained most easily by the distillation of stearic acid. The humidity at the beginning of the process must be expelled by a smart heat, otherwise explosive ebullitions are apt to occur. Whenever the ebullition becomes uniform, the fire is to be moderated.

MARINE ACID. See MURIATIC ACID and HYDROCHLORIC ACID.

MARINE SALT. See SALT.

MARL (*Marne*, Fr.; *Mergel*, Germ.), is a mixed earthy substance, consisting of carbonate of lime, clay, and siliceous sand, in very variable proportions; it is sometimes compact, sometimes pulverulent. According to the predominance of one or other of these three main ingredients, marls may be distributed into calcareous, clayey, and sandy. See LIMESTONE.

MARQUETRY, is a peculiar kind of cabinetwork, in which the surface of wood is ornamented with inlaid pieces of various colors and forms. The *marqueteur* puts gold, silver, copper, tortoise-shell, mother-of-pearl, ivory, horn, &c., under contribution. These substances being reduced to laminae of proper thinness, are cut out into the desired forms by punches, which produce at once the full pattern or mould, and the empty one, which enclosed it; and both serve their separate purposes in marquetry. For the methods of dyeing the woods, &c., see IVORY.

MARTIAL, signifies belonging to iron; from Mars, the mythological name of this metal.

MASSICOT, is the yellow oxide of lead.

MASTIC (Eng. and Fr.; *Mastix*, Germ.), is a resin produced by making incisions in the *Pistacia Lentiscus*, a tree cultivated in the Levant, and chiefly in the island of Chios. It comes to us in yellow, brittle, transparent, rounded tears; which soften between the teeth; with bitterish taste and aromatic smell, and a specific gravity of 1.07. Mastic consists of two resins; one soluble in dilute alcohol; but both dissolve in strong alcohol. Its solution in spirit of wine constitutes a good varnish. It dissolves also in oil of turpentine. See VARNISH.

MATCHES, CHEMICAL. Put 40 grains of phosphorus into a wide-mouthed bottle. Add enough oil of turpentine to cover the phosphorus; then mix in 10 grs. of flower of sulphur. Put the bottle into hot water until the phosphorus is entirely dissolved; stop the mouth of the bottle with a cork, and well shake the whole until it has become cold; afterwards pour off the supernatant oil of turpentine. Into the mixture of phosphorus which remains in the bottle dip the extremities of the matches, and, after some time, when they have become a little dried, dip them again into the following mixture.

Dissolve 30 grains of gum arabic in a small quantity of water; add to it 20 grs. of chlorate of potash, and mix them intimately together; then again add 10 grs. of soot previously mixed with a few drops of spirits of wine.

In about 12 hours the matches will be perfectly dry, when they will ignite on rubbing them over a rough surface.

MATCHES, INSTANTANEOUS LIGHT, *without Sulphur and without Noise.* Boettcher has published the following formula for the preparation of chemical matches, which ignite without noise:—

Take of Gum Arabic	-	-	-	-	16 parts.
Phosphorus	-	-	-	-	9 —
Nitrate of potash	-	-	-	-	14 —
Manganese	-	-	-	-	16 —

Mix, so as to form a perfectly homogeneous mass.

More recently, this chemist, being desirous of making a mass equally good, but at a lower price, fixed on the following formula:—

Take of Phosphorus	-	-	-	-	4 parts.
Nitrate of potash	-	-	-	-	10 —
Carpenter's glue	-	-	-	-	6 —
Minium, or red ochre	-	-	-	-	5 —
Smalt	-	-	-	-	2 —

The glue is cut and soaked in a little water for 24 hours; it is then put into a porcelain mortar, previously heated, so as to cause its liquefaction. The phosphorus is then added, afterwards the nitrate of potash, and lastly the minium and smalt, mixing the ingredients constantly with the pestle, until a perfectly homogeneous mixture is formed which may almost be drawn out in threads.

During this operation the temperature must never be allowed to rise above 167° F., to prevent the inflammation of the particles of phosphorus.

This paste may be applied to wood prepared for the purpose, or to amadou previously dried for eight or twelve hours.

Paper matches may be made, which will afford an agreeable odor on igniting, by wetting slips of paper on both sides with tincture of benzoin, and then applying a small quantity of the above composition to their extremities, by means of a small brush. On rubbing one of these on a rough surface, the mass inflames and ignites the paper without the intervention of a coating of sulphur.

Matches of wood may be made that will inflame without sulphur, by slightly carbonizing the ends of them, by placing them against a red hot plate of iron, and then dipping them into melted wax.

M. Diesel, of Ebersdorf, pupil of M. Wackenroder, has analyzed an excellent inflammable mass, and found the following proportions of ingredients in 100 parts:—

Phosphorus	-	-	-	-	17
Nitrate of potash	-	-	-	-	38
Minium	-	-	-	-	24
Glue	-	-	-	-	21

MATCHES, LUCIFER. According to Dr. R. Boettger, in *Annalen der Chemie und Pharmacie*, vol. xlvii. p. 334, take

Phosphorus	-	-	-	-	4 parts.
Nitre	-	-	-	-	10 —
Fine glue	-	-	-	-	6 —
Red ochre, or red lead	-	-	-	-	5 —
Smalt	-	-	-	-	2 —

Convert the glue with a little water by a gentle heat into a smooth jelly, put it into a slightly warm porcelain mortar to liquefy; rub the phosphorus down through this gelatine at a temperature of about 140° or 150° Fahr.; add the nitre, then the red powder, and lastly the smalt, till the whole forms a uniform paste. To make writing-paper matches, which burn with a bright flame and diffuse an agreeable odor, moisten each side of the paper with tincture of benzoin, dry it, cut it into slips, and smear one of their ends with a little of the above paste by means of a hair pencil. On rubbing the said end after it is dry against a rough surface the paper will take fire, without the intervention of sulphur.

To form lucifer wood matches, that act without sulphur, melt in a flat-bottomed, tin pan as much white wax as will stand one-tenth of an inch deep; take a bundle of wooden matches free from resin, rub their ends against a red hot iron plate till the wood be slightly charred; dip them now in the melted wax for a moment, shake them well on taking them out, and finally dip them separately in the viscid paste. When dry, they will kindle readily by friction.

For the rapid manufacture of the wooden splints for lucifer matches, a patent was granted to Mr. Reuben Partridge, in March, 1842. He employs a perforated metallic plate, having a steel face, strengthened by a bell-metal back; see *figs.* 887, 888. The size of the perforations must depend on that of the desired splints, but they must be as close together as possible, that there may be a very small blank space between them, otherwise the plate would afford too great resistance to the passage of the wood. By this construction, the whole area of the block of wood may be compressed laterally into the countersunk openings, and forced through the holes, which are slightly countersunk to favor the entrance and separation of the wooden fibres.

Fig. 887 represents the face of one of these plates; and *fig.* 888 is a rectangular section through the plate. A convenient size of plate is three inches broad, six inches long, and one thick. The mode of pressing is by fixing the back of the plate against a firm resisting block or bearing, having an aperture equal to the area of the perforations in the plate, and then placing the end of the piece or pieces of wood in the direction of the grain against the face of the plate within the area of the perforated portion. A plunger or lever or other suitable mechanical agent being then applied to the back or reverse end of the piece of wood, it may be forced through the perforations in the plate, being first split as it advances by the cutting edges of the holes, and afterwards compressed and driven through the perforations in the plate, coming out on the opposite side or back of the plate in the form of a multitude of distinct splints, agreeably to the shapes and dimensions of the perforations.—*Newton's Journal*, C. S. vol. xxii. 268.

Manufacture of Lucifers. The first stage in the manufacture of lucifers is the cutting the wood, which is done according to the extent of the manufactory, either by hand or by machinery. This, as well as the subsequent process of counting and placing the matches in frames, is in itself necessarily free from any inconvenience or evil consequences; nor does it appear that the third stage, which consists in melting the sulphur and dipping the heads of the matches in it, produces any inconvenience. The fourth, fifth, sixth, and seventh stages comprise the grinding, mulling and mixing of the explosive compound; the process of dipping the matches in it, the counting and boxing. The dipping, counting, and packing, appear to be, according to Mr. Geist, the only departments in which the workpeople are in any way affected with peculiar complaints; we would even limit the appearance of the jaw disease to those engaged in dipping; at least all that we have examined on the subject were unanimous as to the fact that dippers only were attacked. There is a certain degree of secrecy observed relative to the proportions of the composition; and the mixture of the materials is generally performed by the proprietor of the manufactory, or by a confidential workman. Chlorate of potash is considered an essential ingredient in England; but in the manufactories at Nürnberg it has not been employed for a number of years, as its explosive properties much endangered the safety of the buildings and the limbs of the workmen.

The composition used in Nürnberg consists of one-third of phosphorus, of gum arabic (which is eschewed by English manufacturers on account of its hygrometric property), of water, and of coloring matter, for which either minium or Prussian blue

is employed. If ignition be required without a flame, the quantity of phosphorus is diminished, or nitrate of lead is added. The mixing is conducted in a water bath, and during this process, and as long as the phosphorus is being ground or "mullered," copious fumes are evolved. The dipping is performed in the following manner:—The melted composition is spread upon a board covered with cloth or leather, and the workman dips the two ends of the matches alternately that are fixed in the frame; and as this is done with great rapidity, the disengagement of fumes is very considerable, and the more liable to be injurious, as they are evolved in a very concentrated form close to the face of the workmen. This department is generally left to a single workman; and the average number that he can dip in an hour, supposing each frame to hold 3,000 matches, would be 1,000,000.

After the matches have been dipped, they require to be dried. This is generally done in the room in which the former process is carried on; and as a temperature of from 80° to 90° Fahr. is necessary, the greatest quantity of fumes is evolved at this stage. When the matches are dried, the frames are removed from the drying room, and the lucifers are now ready to be counted out into boxes. As this is done with great rapidity, they frequently take fire, and, although instantly extinguished in the sawdust or the water which is at hand, the occurrence gives rise to an additional and frequent evolution of fumes.

MATRASS, is a bottle with a thin egg-shaped bottom, much used for digestions in chemical researches.

MATTE, is a crude black copper reduced, but not refined from sulphur and other heterogeneous substances.

MEADOW ORE, is conchoidal bog iron ore.

MEATS, PRESERVED. The interest which has of late attached to the subject of such meats, warrants us in bringing under examination the principles and practice on which this important branch of industry is based. The art itself is of modern invention, and differs in every respect from the old or common modes of preserving animal food. These, as is well known, depend on the use of culinary salt, saltpetre, sugar, or similar substances, which, when in solution, do not possess the power of absorbing oxygen gas, and therefore cut off effectually all access of air to the meat they protect. It might be imagined that water alone would answer this purpose; but the contrary is the case, for pure water absorbs oxygen, and is, therefore, all the less adapted for preserving meat, in proportion as it is free from saline matter, since it is then so much the more capable of combining with oxygen gas. Thus, snow, which is pure water crystallized, has a power of producing the panary fermentation when mixed with flour; and this it is able to do in consequence of the large quantity of gaseous oxygen which it contains. Similarly, rain water, and especially dew, will bring on the putrefaction of animal matters much sooner than spring water; and the vulgar prejudice respecting the effect of the moon's rays in accelerating the corruption of meat, is, beyond doubt, dependent upon the fact, that during clear moonlight nights, there is always a large deposition of dew; and this having fallen in a minutely divided state, possesses the largest amount of free oxygen, which pure or distilled water is capable of absorbing from the atmosphere, and, therefore, has a proportionate power of decomposing,—just as it also has of bleaching.

Thus far our remarks have been applied solely to raw or uncooked meats; but the practical bearing of the object which we have in hand really points to those which are more or less cooked or preserved. It is with reference to provisions of this kind, that a parliamentary inquiry is now in progress; and we cannot do better than show the great importance of such a subject to a maritime nation like Great Britain, by stating, that these provisions, when sound, are an absolute preventive of sea-scurvy,—a disease said, on good authority, to have destroyed more life, and to have done more damage to our navy, than all the enemies and tempests which that navy ever encountered. We need not go far in search of evidence to prove the fearful havoc caused by this disease; for we are well furnished by the history of Admiral Anson's memorable expedition, to damage the interests of Spain in the Pacific Ocean, by intercepting the annual treasure-ship or galleon on her return to Europe. In spite of every thing that care and experience could do, Anson tells us that he lost, in all, fully four-fifths of his people by scurvy. Of 400 men with whom the "Centurion" departed from England, only 200 lived to reach the island of Juan Fernandez, and no more than 8 of these were capable of doing duty; and but for a supply of others at St. Helena, there would not have been strength remaining to carry the ship to her anchorage. After describing, in the most pathetic manner, the dreadful sufferings of his crew, and rejoicing at the improvement caused by the sojourn at Juan Fernandez, the writer concludes,—“I therefore shall sum up the total of our loss since our departure from England, the better to convey some idea of our past sufferings and our present strength. We had buried on board the 'Centurion,' since leaving St. Helena, 292 men, and had remaining on board 214. This will, doubtless, appear a most extraordinary mortality; but yet, on board the 'Gloucester' (his other ship of war) it had been much greater: for, out of a much smaller crew than ours, they had buried the same number, and had only 82 remaining alive. It might," con-

tinues Anson, "have been expected that, on board the 'Tryal' (a provision ship), the slaughter would have been most terrible; but it happened otherwise, for she escaped more favorably than the rest, since she *only* buried 42, and has now 39 remaining." The real object of the voyage was, however, not yet commenced; though out of 960 men, with which the three vessels left England, 626 were dead before this time.

It is almost superfluous to multiply instances of the same kind; though, in order to demonstrate the great utility of preserved meats in the navy, we shall give two or three other examples, as there is evidently a desire, in certain quarters, to get rid of a trifling labor and responsibility, by excluding this class of provisions altogether from our victualling departments. In October, 1788, the fleet of Admiral Keppell came into harbor, and, before the end of December had sent 3,600 sick to the hospital at Haslar. In 1779, the channel fleet under Sir C. Hardy, sent 2,500 to the hospital, and retained more than 1,000 on board for want of hospital accommodation. Within 4 months during a subsequent year, 8,064 were sent to Haslar, and Sir H. Hawkins asserts, that, within the space of 20 years, to his own knowledge, not less than 10,000 men had died of scurvy. When Admiral Geary's fleet returned to Portsmouth, after a ten weeks' cruise in the Bay of Biscay, 2,400 men were ill of the scurvy; and the gross number of admissions into the hospital that year was 11,732, of whom 909 died. Now the highest medical authorities in this kingdom, and also on the continent, have all expressed the opinion that this fearful disease and mortality is altogether caused by the use of salt provisions; and the evidence of a host of navy surgeons and officers can be adduced to corroborate the truth of this view; therefore, not only motives of humanity, but also of self-interest, imperatively demand that, wherever unsalted provisions can be used, their employment should be insisted on, by the voice of the entire nation. Such being the case, it becomes necessary for us to inquire how far the art of preserving unsalted provisions has reached that degree of uniformity, and certainty of result, which alone can warrant their introduction into the navy.

The first successful attempt at the preservation of unsalted meats is of French origin, and due to the inventive skill of M. Appert. This gentleman, so long ago as the year 1810, received from the board of Arts and Manufactures of Paris the sum of 12,000 francs for his discovery of a mode of preserving animal and vegetable substances; the results of which had been then amply attested, by a prolonged experience in the French navy. Shortly after this period, Appert induced a Mr. Durant to visit London, for the purpose of taking out a patent; and this was accordingly done towards the end of the year 1811. In this patent, however, the claims were ridiculously wide, so much so, that the patent-right was subsequently infringed with impunity. The claims included all kinds of fruit, meat, and vegetables, when subjected to the action of heat in closed vessels, more or less freed from air. As, however, the Society of Arts in London had presented in 1807, a premium to a Mr. J. Suddington, for "a method of preserving fruit without sugar for house or sea stores"—which method is exactly the same as that of M. Appert,—the validity of Durant's patent was at once called in question. Nevertheless so satisfactory were the results, when applied to animal food, or mixed provisions, that the patent was eventually purchased from Durant by Messrs. Donkin, Hall and Gamble, for the sum of 1000*l.*; and the firm, thus established, became at once the sole manufacturers of preserved meats in this country. The process of Appert was, however, extremely defective in a manufacturing point of view. Nothing but glass bottles were to be used for containing the meats, and M. Appert remarks,—“I choose glass for this purpose, as being the most impenetrable to air, and have not ventured to make any experiment with a vessel made of any other substance.” Of course, the fragility of this material, and the great difficulty of hermetically sealing the bottle with corks, threw an incalculable impediment in the way of the process as a commercial undertaking. Nor was it until after a long series of difficult and expensive experiments that Messrs. Donkin, Hall and Gamble, were able to overcome the primary difficulties of this invention, and produce provisions successfully preserved in tin plate vessels. Since that time but little alteration, and less improvement, has been made in the art, though its principles are far more complex than has hitherto been supposed.

From the researches of M. Gay Lussac, it appeared that the absence of oxygen was requisite to prevent fermentation; but it is now certain, that oxygen may be present with fermentable matters without producing any effect whatever. As there are substances and conditions which cause or accelerate fermentation, so there are others which prevent or retard it; and this is true, whatever be the nature of the fermentation. Although, therefore, the exclusion of oxygen be a means of preventing putrefaction, it is not the only means, nor is it, indeed, the easiest or simplest in application. The process of Appert certainly does not depend upon the exclusion of oxygen from the provisions he preserved, nor is this principle included in the improved process still practised, with such marked success, by the well known firm of Gamble, at Cork. We have had an opportunity of examining the air contained in perfectly sound canisters of *Gamble's provisions*, and have constantly found it to afford distinct evidences of the

presence of oxygen gas, even in cases several years old. The quantity is, indeed, much less than that in atmospheric air, but its existence is clear and undeniable. Hence we must look for some other theory than that which refers putrefaction to the presence of uncombined oxygen, if we wish to speculate upon the *modus operandi* of Gamble's method. Appert seems to have had a decided doubt as to the sufficiency of the oxygen theory, for he tells us that "fire has a peculiar property, not only of changing the combination of the constituent parts of vegetable and animal productions, but also of retarding, for many years at least, if not of destroying altogether, the natural tendency of these same products to decomposition." And this opinion is confirmed from many startling facts, which cannot be reconciled to the supposition that oxygen is the sole or even principal agent of decomposition. Thus milk, which has been merely scalded, will keep much longer from the effect of this process, even though freely exposed to, or purposely impregnated with, oxygen gas. All kinds of meat exhibit a similar result. Again, very minute quantities of some mineral substances, as arsenic and corrosive sublimate, or of organic matters, such as creosote, naphtha, and the volatile oils, have the same action when applied to meat or vegetables; and generally speaking, any thing which will coagulate albumen has a preservative power upon organic substances. So that oxygen appears to exert a decomposing force only when one or other of the forms of soluble albumen is present. Now, the method of Appert, as improved by Gamble (for the firm of Donkin, Hall, and Gamble no longer exists), is to render the albumen of the meat or vegetable insoluble, and therefore scarcely, if at all, susceptible of the action of atmospheric oxygen. By this means the total exclusion of air from the tin cases is rendered unnecessary, for even if a small quantity of air remain in the case, it will exert no more influence than happens to a piece of coagulated albumen, or hard boiled white of egg, which, as is well known, may be exposed to the air for years without sensible alteration, though in its uncoagulated state it immediately putrefies. If, therefore, we were desired in a few words to express the essential characteristics of Gamble's process, it would not be by referring to the exclusion of air, but to the thorough coagulation of the albumen, that we should look for a satisfactory description. In this process the meat, more or less cooked, is placed, with a quantity of gravy, in a tin vessel, capable of being hermetically sealed with solder; it is then heated, for sometime in a bath of muriate of lime, and the aperture neatly soldered up. After this it is again exposed to the action of the heated bath for a period, which varies with the size and nature of the contents of the vessels; and to prove that this latter operation is really the most important of the whole, it sometimes happens that cases which have begun to decompose are opened, resoldered, and again submitted to the muriate of lime bath, with the most perfect success, as regards the ultimate result. There is, however, no little difficulty in effecting the thorough coagulation of albumen by heat, when the quantity of albumen is small in proportion to the water present. A long continued and rather high temperature is then needed; more especially if vinegar or lactic acid be present in the fluid, as these tend to retain the albumen in solution: much must therefore depend upon practical experience; and it is not improbable that a heat in the bath but little higher than that of boiling water, would afford more uniform results, than would be obtained with a boiling saturated solution of muriate of lime. This subject will, however, be more fully discussed when speaking of Goldner's processes.

Although by no means free from occasional failures and certainly requiring improvement, the system of Gamble has in practice worked well; and provisions have been kept in this way, for a period of more than twenty-six years, without the slightest alteration in their particular qualities; and so well is this fact known and appreciated by British naval officers in general, that few vessels now leave our ports without at least a proper supply for cabin use. It was found by Sir John Ross that a number of those cases of these preserved provisions left for many years upon Fury beach and exposed to excessive variations of temperature, were, nevertheless, perfectly sound and wholesome as food when opened.

Guided probably by theoretical considerations, and too much impressed with the necessity of excluding oxygen, a Mr. Goldner, some few years ago, adopted the idea originally conceived by Sir Humphry Davy, of enclosing cooked provisions in a complete vacuum. For this purpose the provisions, slightly cooked on the surface, were enclosed in canisters, similar to those of Gamble, but stronger, and provided with a small opening in the cover. At this moment a slight condensation was effected by the application of a cold and damp rag or sponge, and simultaneously with this the small opening was soldered up. In theory, nothing could seem better adapted to insure success; but, from the late parliamentary disclosures, it is evident that the practical working of the invention affords any thing but a satisfactory result. Nor is there much difficulty in conceiving how this may arise, as in the first place the application of a sudden heat to non-conducting materials is almost certain to give rise to that peculiar condition of water called the spheroidal state, and by which the interior of

the meat will be as thoroughly protected from the effect of heat as if no heat were applied. Hence, even though steam in abundance may issue from the small opening in the cover, this is no proof that the meat in the centre of the vessel is even warmed; and still less does it warrant the supposition that the soluble albumen is thoroughly coagulated; and without which, as we have stated, preservation is scarcely possible. But, in addition to this, the application of a damp rag, in the way described, is, of all others, that by which a portion of air is most likely to be drawn into the vessel at the very moment when its total expulsion is taken for granted; and both these circumstances are more liable to happen with large than with small canisters. If, however, the meat has been but partially cooked, in consequence of the water in it assuming the spheroidal condition, and, at the same time, atmospheric oxygen is included, there can be no manner of doubt that putrefaction will occur, and run its course with the same rapidity as if no process whatever had been employed to prevent it. That water so situated in the substance of flesh is extremely prone to take on the form called spheroidal, needs no other proof than that the human hand may be deliberately passed through molten brass or iron with perfect impunity, and without even sensibly warming the fingers, as illustrated by M. Boutigny. It is not, therefore, enough to expose these canisters of provisions to heat, unless that heat be so gradually applied as to prevent the assumption of a spheroidal state by the watery portion of the food; and we cannot help thinking that much of the disappointment and loss, consequent upon this kind of manufacture, has its origin in a want of attention to the above circumstance. Where all power of circulation is prevented, as in the instance of these semi-solid meats, the tendency of the part in immediate contact with the source of heat to acquire a temperature capable of inducing the spheroidal condition, must be very great indeed; and hence, in speaking of the muriate of lime bath, employed by Gamble, we took occasion to hint, that more uniform results might perhaps be obtained by a moderate than by a high temperature. The probability is, that no advantage is gained by exceeding 220° Fahr.; and viewing the subject chemically, even this seems too high, where time is less an object than perfection of manufacture.

It now remains only to offer a few remarks on the cooking of animal food, and its application to the wants of humanity. If flesh be digested for a short time in cold water or brine, it parts with several of its most important constituents, and therefore the practice of large and repeated washing is an unwise and foolishly fastidious operation. Cold water dissolves from meat its soluble phosphates, its lactic acid, its kreatine, and kreatinine, as well as its albumen. Without these constituents, however, the meat neither is nor can be fitted to supply the muscular wear and tear of the human frame. In fact, one of these substances (kreatine) has evidently a singular connection with muscular energy, as it exists in greatest quantity in the flesh of animals most remarkable for muscular power and activity. To exclude it, therefore, is to introduce an element of weakness in the dietary of our seamen, that cannot fail, in the long run, to show itself; and hence the enormous prostration of strength which accompanies the sea-scurvy; for it happens that, as kreatine is soluble in brine, but little of this valuable element remains in the contracted and solidified mass, known by the name of salt junk, and employed as food in the Navy, upon much the same principle as that ascribed to alligators, who swallow stones to appease the cravings of an empty stomach. If, however, there is an error in the commencement of our Navy's victualling, there is still greater in the treatment of salt junk by its prejudiced and ill-informed consumers. Having had its albumen and other valuable matters removed by a cold solution of common salt, the junk is next deprived of its gelatine and osmazome, by the action of boiling water; and this gelatine, which, with the kreatine and lactic acid, would greatly facilitate the process of digestion, is thrown away as worthless; and nothing but a hard mass of fibrine, scarcely, if at all, susceptible of assimilation by the powers of the animal economy, remains to give the appearance of food to the product, and, as it were, keep the word of promise to the eye, "to break it to the hope." The following quotation from Liebig's *Researches on the Chemistry of Food* may fitly occupy a place here: "It is obvious, that if flesh employed as food is again to become flesh in the body—if it is to retain the power of reproducing itself in its original condition—none of the constituents of raw flesh ought to be withdrawn from it during its preparation for food. If its consumption be altered in any way—if one of the constituents which belong essentially to its constitution be removed—a corresponding variation must take place in the power of that piece of flesh to reassume, in the living body, the original form and quality on which its properties in the living organism depend." It follows from this, that boiled flesh when eaten *without* the soup formed in boiling it, is so much the *less* adapted for nutrition, the greater the quantity of water in which it has been boiled, and the longer the duration of the boiling.

Under such circumstances, we cannot wonder that in spite of the acknowledged purity of sea-water, disease to a large extent should prevail in our Navy, and that when any *active malady* makes its appearance, the mortality should greatly exceed that of the

army under similar circumstances. This is a more natural sequence of the system pursued with regard to provisions; and so far from abandoning altogether the employment of preserved meats from the casual putrefaction of a few cases, it seems to us that a wise government would rather seek to run all this inconvenience, by calling in the aid of science, than fall back into a supine condition, when the interest of the nation so loudly calls for activity. After all, however, we can find no proof that these preserved provisions have failed, except in the case of Goldner; for there are many other manufacturers, both in this country and in France, whose productions no more warrant the ban of exclusion, than a trifling accident deserves to be deemed a deliberate crime. If failure be a sufficient reason for interdicting further operations, how shall we account for the persevering assiduity of our dock yard authorities in respect to ship-building? We sincerely hope that the parliamentary committee, now sitting, will not separate until the whole subject of preserved provisions has been fully and impartially investigated in all its details.

MEDALS. For their composition, see **BRONZE** and **COPPER**.

The Industrial Exhibition of 1851 has called into requisition, among others, the skilled labor of the medallist die-sinker. As a consequence, medals of all kinds and prices are being produced. A medal die is thus formed:—Steel of an uniform texture and kind being selected, it is forged, softened by annealing, and the face and cheek for the collar turned. The design approved of, the die-sinker proceeds to cut away those parts of the greatest depth by means of small chisels: the more minute details are taken out by gravers, chisel-edged, and gauged steel tools fitted into wood handles very short, and to fit the palm of the hand. As the work proceeds, proofs are taken in wax; when defective in form the cutting is corrected, deficient in relief, it is sunk deeper. It will of course be borne in mind that, what will be relieve in the medal, is intaglio in the die. The inscription is introduced by means of small letter-punches. Then follows the hardening of the die, a stage of the business the most critical, as a defect in the steel will at once be made apparent thereby, and the labor of months rendered useless in a few minutes. If the die endures this, it has only another test, viz., the making of a "hub," or copy of the die in steel, and used for the correction of the duplicate copies of the die. The danger in this case arises from the want of uniformity of hardness. If irregular, one portion of the die must suffer, and become valueless.

Medal-making or stamping is thus carried on:—The press consists of a large and close threaded screw, to the top of which a large wheel is attached horizontally. The bed of the press is fitted with screws to secure the die in its place; when this is done the collar which gives the thickness of the medal is fitted on, the die forming the reverse of the medal is attached to the screw; a blank (a piece of metal cut out to form the medal) is then introduced. Motion is imparted to the wheel, which operates on the screw; a blow is given, and if the impression is soft and shallow, a medal is produced; but if deep, repeated blows are given to bring the impression up. When bronze or silver is the material in which the medal is to be produced, as many as 20 or even 30 blows are necessary. The medal is then taken out of the press, the edge turned, and the operation is complete.

By collar die, is meant that portion which gives the thickness to the medal or coin to be struck. All medal dies are of three parts, viz., the reverse, obverse, and collar. The smaller class of dies are cut in steel entirely, the larger kinds for brass foundry and other purposes are "laid" or covered with steel on a foundation of iron. When indentations occur, the die is what is called "fullered," or hollowed, and the steel follows the same in a parallel thickness.

MEERSCHAUM (Germ.; *sea-froth*, Eng.; *Ecume de Mer Magnésique carbonatée siliceuse*, Fr.) is a white mineral, of a somewhat earthy appearance, always soft, but dry to the touch, and adhering to the tongue. Specific gravity, 2.6 to 3.4; affords water by calcination; fuses with difficulty at the blowpipe into a white enamel; and is acted upon by acids. It consists, according to Klaproth, of silica, 41.5; magnesia, 18.25; water and carbonic acid, 39. Other analysts give, silica 50, magnesia 25, water 25. It occurs in veins or kidney-shaped nodules, among rocks of serpentine, at Egrihas, in the island of Negropont, Eski-Sehehir in Anatolia, Brussa at the foot of Mount Olympus, at Baldissero in Piedmont, in the serpentine veins of Cornwall, &c.

When first dug up, it is soft, greasy, and lathers like soap; and is on that account used by the Tartars in washing their linen. The well known Turkey tobacco-pipes are made from it, by a process analogous to that for making pottery ware. The bowls of the pipes, when imported into Germany, are prepared for sale by soaking them first in tallow, then in wax, and finally by polishing them with shave-grass.

MELLITE (Eng. and Fr.; *Honigstein*, Germ.) See **HONEYSTONE**.

MELLITIC ACID, which is associated with alumina in the preceding mineral, crystallizes in small colorless needles, is without smell, of a strongly acid taste, permanent in the air, soluble in water and alcohol, as also in boiling hot concentrated sulphuric acid, but is decomposed by hot nitric acid, and consists of 50.21 carbon, and

49-79 oxygen. It is carbonized at a red heat, without the production of any inflammable oil.

MELLON is a new compound of carbon and azote, discovered by M. Liebig, by heating bi-sulpho-cyanide of mercury. The mellon remains at the bottom of the retort under the form of a yellow powder.

MENACHANITE, an ore of titanium, found in the bed of a rivulet which flows into the valley Menacan, in Cornwall.

MERCURY or QUICKSILVER. This metal is distinguished by its fluidity at common temperatures; its density=13.6; its silver blue lustre; and its extreme mobility. A cold of 39° below zero of Fahrenheit, or -40° Cent., is required for its congelation, in which state its density is increased in the proportion of 10 to 9, or it becomes of spec. grav. 15.0. At a temperature of 656° F. it boils and distils off in an elastic vapor; which, being condensed by cold, forms purified mercury.

Mercury combines with great readiness with certain metals, as gold, silver, zinc, tin, and bismuth, forming, in certain proportions, fluid solutions of these metals. Such mercurial alloys are called *amalgams*. This property is extensively employed in many arts; as in extracting gold and silver from their ores; in gilding, plating, making looking-glasses, &c. Humboldt estimates at 16,000 quintals, of 100 lbs. each, the quantity of mercury annually employed at his visit to America, in the treatment of the mines of New Spain; three fourths of which came from European mines.

The mercurial ores may be divided into four species:—

1. *Native quicksilver*.—It occurs in most of the mines of the other mercurial ores, in the form of small drops attached to the rocks, or lodged in the crevices of other ores.

2. *Argentiferous mercury, or native silver amalgam*.—It has a silver white color, and is more or less soft, according to the proportion which the mercury bears to the silver. Its density is sometimes so high as 14. A moderate heat dissipates the mercury, and leaves the silver. Klaproth states its constituents at silver 36, and mercury 64, in 100; but Cordier makes them to be, 27½ silver, and 72½ mercury. It occurs crystallized in a variety of forms. It has been found in the territory of Deux-Ponts, at Rozenau and Niderstana, in Hungary, in a canton of Tyrol, at Sahlberg in Sweden, at Kolyvan in Siberia, and at Allemont in Dauphiny; in small quantity at Almaden in Spain, and at Idria in Carniola. By the chemical union of the mercury with the silver, the amalgam, which should by calculation have a spec. grav. of only 12.5, acquires that of 14.11, according to M. Cordier.

3. *Sulphuret of mercury*, commonly called Cinnabar, is a red mineral of various shades; burning at the blowpipe with a blue flame, volatilizing entirely with the smell of burning sulphur, and giving a quicksilver coating to a plate of copper held in the fumes. Even the powder of cinnabar rubbed on copper whitens it. Its density varies from 6.9 to 10.2. It becomes negatively electrical by friction. Analyzed by Klaproth, it was found to consist of mercury 84.5, sulphur 14.75. Its composition, viewed as a bisulphuret of mercury, is, mercury 86.2, sulphur 13.8. The finest crystals of sulphuret of mercury come from China, and Almaden in Spain. These contain, according to Klaproth, 85 per cent. of mercury.

A *bituminous sulphuret of mercury* appears to be the base of the great exploration of Idria; it is of a dark liver-red hue; and of a slaty texture, with straight or twisted plates. It exists in large masses in the bituminous schists of Idria. M. Beurard mentions also the locality of Munster Appel, in the dutchy of Deux-Ponts, where the ore includes impressions of fishes, curiously spotted with cinnabar.

The compact variety of the Idria ore seems very complex in composition, according to the following analysis of Klaproth:—Mercury, 81.8; sulphur, 13.75; carbon, 2.3; silica, 0.65; alumina, 0.55; oxyde of iron, 0.20; copper, 0.02; water, 0.73; in 100 parts. M. Beurard mentions another variety from the Palatinate, which yields a large quantity of bitumen by distillation; and it was present in all the specimens of these ores analyzed by me for the German Mines Company. At Idria and Almaden the sulphurets are extremely rich in mercury.

4. *Muriated mercury, or the Chloride of mercury*, commonly called Horn mercury. This ore occurs in very small crystals of a pearl-gray or greenish-gray color, or in small nipples which stud, like crystals, the cavities, fissures, or geodes among the ferruginous gangues of the other ores of mercury. It is brittle, and entirely volatile at the blow-pipe, characters which distinguish it from horn silver.

The geological position of the mercurial ores, in all parts of the world, is in the strata which commence the series of secondary formations. Sometimes they are found in the red sandstone above the coal, as at Menildot, in the old dutchy of Deux-Ponts, at Durasno in Mexico, at Cuenca in New Granada, at Cerros de Gauzan and Upar in Peru; in the subordinate porphyries, as at Deux-Ponts, San Juan de la Chica in Peru, and at Cerro-del-Fraile, near the town of San Felipe; they occur also among the strata below, or subordinate to the calcareous formation, called *zechstein*, in Germany, or

among the accompanying bituminous schists, as at Idria in Carniola; and, lastly, they form masses in the zechstein itself. Thus, it appears that the mercurial deposits are confined within very narrow geological limits, between the calcareous beds of zechstein, and the red sandstone. They occur at times in carbonaceous nodules, derived from the decomposition of mosses of various kinds; and the whole mercurial deposit is occasionally covered with beds of charcoal, as at Durasno.

They are even sometimes accompanied with the remains of organic bodies, such as casts of fishes, fossil shells, silicified wood, and true coal. The last fact has been observed at Potzberg, in the works of Drey-Koenigszug, by M. Brongniart. These sandstones, bituminous schists, and indurated clays, contain mercury both in the state of sulphuret and in the native form. They are more or less penetrated with the ore, forming sometimes numerous beds of very great thickness; while, in the more ancient or the primitive formations, these ores exist only in very small quantity associated with tin. Mercury is, generally speaking, a metal sparingly distributed in nature, and its mines are very rare.

The great exploitations of Idria in Friuli, in the county of Goritz, were discovered in 1497, and the principal ore mined there is the bituminous sulphuret. The workings of this mine have been pushed to the depth of 280 yards. The product in quicksilver might easily amount annually to 6000 metric quintals=600 tons British; but, in order to uphold the price of the metal, the Austrian government has restricted the production to 150 tons. The memorable fire of 1803 was most disastrous to these mines. It was extinguished only by drowning all the underground workings. The sublimed mercury in this catastrophe occasioned diseases and nervous tremblings to more than 900 persons in the neighborhood.

Pliny has recorded two interesting facts: 1. that the Greeks imported red cinnabar from Almaden 700 years before the Christian era; and 2. that Rome, in his time, annually received 700,000 pounds from the same mines. Since 1827, they have produced 22,000 cwt. of mercury every year, with a corps of 700 miners and 200 smelters; and, indeed, the veins are so extremely rich, that though they have been worked pretty constantly during so many centuries, the mines have hardly reached the depth of 330 yards, or something less than 1000 feet. The lode actually under exploration is from 14 to 16 yards thick; and it becomes thicker still at the crossing of the veins. The totality of the ore is extracted. It yields in their smelting works only 10 per cent. upon an average, but there is no doubt, from the analysis of the ores, that nearly one half of the quicksilver is lost, and dispersed in the air, to the great injury of the workmen's health, in consequence of the barbarous apparatus of aludels employed in its sublimation; an apparatus which has remained without any material change for the better since the days of the Moorish dominion in Spain. M. Le Play, the eminent *Ingenieur des Mines*, who published, in a recent volume of the *Annales des Mines*, his *Itinéraire* to Almaden, says, that the mercurial contents of the ores are *notablement plus élevées* than the product.

These veins extend all the way from the town of Chillon to Almadenejos. Upon the borders of the streamlet Balde Azogues, a black slate is also mined which is abundantly impregnated with metallic mercury. The ores are treated in 13 double furnaces, which I shall presently describe. "Le mercure," says M. Le Play, "a sur la santé des ouvriers la plus funeste influence, et l'on ne peut se défendre d'un sentiment pénible en voyant l'empressement avec lequel des jeunes gens, pleins de force et de santé, se disputent la faveur d'aller chercher dans les mines, des maladies cruelles, et souvent une mort prématurée. La population des mineurs d'Almaden méritent le plus haut intérêt." These victims of a deplorable mismanagement are described as being a laborious, simple-minded, virtuous race of beings, who are thus condemned to breathe an atmosphere impregnated far and near with the fumes of a volatile poison, which the lessons of science, as I shall presently demonstrate, might readily repress, with the effect of not only protecting the health of the population, but of vastly augmenting the revenues of the state.

These celebrated mines, near to which lie those of *Las Cuebas* and of *Almadenejos*, were known to the Romans. After having been the property of the religious knights of *Calatrava*, who had assisted in expelling the Moors, they were farmed off to the celebrated *Fugger* merchants of Augsburg; and afterwards explored on account of the government, from the date of 1645 till the present time. Their produce was, till very lately, entirely appropriated to the treatment of the gold and silver ores of the new world.

The mines of the *Palatinate*, situated on the left bank of the Rhine, though they do not approach in richness and importance to those of Idria and Almaden, merit, however, all the attention of the government that farms them out. They are numerous, and varied in geological position. Those of Drey-Koenigszug, at Potzberg, near Kussel, deserve particular notice. The workings have reached a depth of more than 220 yards; the ore being a sandstone strongly impregnated with sulphuret of mercury. The produce of these mines is estimated at about 30 tons per annum.

There are also in Hungary, Bohemia, and several other parts of Germany, some considerable exploitations of mercury, the total produce of which is valued at about 30 or 40 tons on an average of several years.

The mines of Guanavelica, in Peru, are the more interesting, as their products are directly employed in treating the ores of gold and silver, which abound in that portion of America. These quicksilver mines, explored since 1570, produced, up to 1800, 53,700 tons of that metal; but the actual produce of the explorations of these countries was, according to Helms, about the beginning of this century, from 170 to 180 tons per annum.

In 1782, recourse was had by the South American miners to the mercury extracted in the province of Yun-nan, in China.

The metallurgic treatment of the quicksilver ores is tolerably simple. In general, when the sulphuret of mercury, the most common ore, has been pulverized, and sometimes washed, it is introduced into retorts of cast-iron, sheet-iron, or even stoneware, in mixture with an equal weight of quicklime. These retorts are arranged in various ways.

Prior to the 17th century, the method called *per descensum* was the only one in use for distilling mercury; and it was effected by means of two earthen pots adjusted over each other. The upper pot, filled with ore, and closed at the top, was covered over with burning fuel; and the mercurial vapors expelled by the heat, passed down through small holes in the bottom of the pot, to be condensed in another vessel placed below. However convenient this apparatus might be, on account of the facility of transporting it, wherever the ore was found, its inefficiency and the losses it occasioned were eventually recognised. Hence, before 1635, some smelting works of the Palatinate had given up the method *per descensum*, which was, however, still retained in Idria; and they substituted for it the furnaces called *galleries*. At first, earthenware retorts were employed in these furnaces; but they were soon succeeded by iron retorts. In the Palatinate this mode of operating is still in use. At Idria, in the year 1750, a great distillatory apparatus was established for the treatment of the mercurial ores, in imitation of those which previously existed at Almaden, in Spain, and called *aludel-furnaces*. But, since 1794, these aludels have been suppressed, and new distillatory apparatus have been constructed at Idria, remarkable only for their magnitude; exceeding, in this respect, every other metallurgic erection.

There exist, therefore, three kinds of apparatus for the distillation of mercury: 1. the furnace called a *gallery*; 2. the furnace with *aludels*; and 3. the large apparatus of Idria. I shall describe each of these briefly, in succession.

1. *Furnace called Gallery of the Palatinate.*—The construction of this furnace is disposed so as to contain four ranges, *a a', b b'*, of large retorts, styled cucurbits, of cast-iron, in which the ore of mercury is subjected to distillation. This arrangement is shown in *fig. 889*, which presents a vertical section in the line *a b* of the ground plan, *fig. 890*. In the ground plan, the roof *e e'* of the furnace (*fig. 889*) is supposed to be lifted off, in order to show the disposition of the four ranges of cucurbits upon the grate *c f*, *figs. 889, 890*, which receives the pit-coal employed as fuel. Under this grate extends an ash-pit *d*. *Fig. 891*, which exhibits an elevation of the furnace, points out this ash-pit, as well as one of the two doors *c*, by which the fuel is thrown upon the grate

c f. Openings *e e'*, (*fig. 889*), are left over the top arch of the furnace, whereby the draught of air may receive a suitable direction. The grate of the fireplace extends over the whole length of the furnace, *fig. 890*, from the door *e* to the door *f*, situated at the opposite extremity. The furnace called *gallery* includes commonly 30 cucurbits, and in some establishments even 52. Into each are introduced from 56 to 70 pounds of ore, and 15 to 18 pounds of quicklime, a mixture which fills no more than two thirds of the cucurbit; to the neck a stoneware receiver is adapted, containing water to half its height.

The fire, at first moderate, is eventually pushed till the cucurbits are red hot. The operation being concluded, the contents of the receivers are poured out into a wooden bowl placed upon a plank above a bucket; the quicksilver falls to the bottom of the bowl, and the water draws over the black mercury, for so the substance that coats

the inside of the receivers is called. This is considered to be a mixture of sulphuret and oxide of mercury. The black mercury, taken out of the tub and dried, is distilled anew with excess of lime; after which the residuum in the retorts is thrown away, as useless.

Aludel furnaces of Almaden.—Figs. 892 and 893 represent the great furnaces with aludels in use at Almaden, and anciently in Idria; for between the two establishments there was in fact little difference before the year 1794. Figs. 892 and 895 present two vertical sections; figs. 893 and 894 are two plans of two similar furnaces, conjoined in

a little inclined towards the intermediate wall *m*. In each range the aludel placed at the line *t m v* of fig. 893 that is to say, at the lowest point, *g*, figs. 892, 895, is pierced with

a hole. Thereby the mercury which had been volatilized in *d*, if it be already condensed by the cooling in the series of aludels *f g*, may pass into the corresponding gutter, next

into the hole *m*, fig. 893, and after that into the wooden pipes *h h'*, fig. 892, which conduct it across the masonry of the terrace into cisterns filled with water; see *q*, fig. 894, which is the plan of fig. 895.

The portion of mercury not condensed in the range of aludels, *f g*, which is the most

considerable, goes in the state of vapor, into a chamber *k*; but in passing under a partition *l l*, a certain portion is deposited in a cistern *i*, filled with water. The greater part of the vapors diffused in the chamber *k* is thereby condensed, and the mercury falls down upon the two inclined planes which form its bottom. What may still exist as vapor passes into an upper chamber *k'*, by a small chimney *n*. On one of the sides of this chamber there is a shutter which may be opened at pleasure from below upwards, and beneath this shutter, there is a gutter into which a notable quantity of mercury collects. Much of it is also found condensed in the aludels. These facts prove that this process has inconveniences which have been tried to be remedied by the more extensive but rather unchemical grand apparatus of Idria.

Details of the aludel apparatus: 25 are set in each of the 12 ranges, seen in *fig. 894*, constituting 300 pear-shaped stoneware vessels, open at both ends, being merely thrust into one another, and luted with loam. What a multitude of joints, of which a great many must be continually giving way by the shrinkage of the luting, whereby the mercurial fumes will escape with great loss of product, to poison the air!

a, is the door of the fire-place; *c*, the perforated arches upon which the ore is piled in the chamber *e*, through the door *d*, and an orifice at top; the latter being closed during the distillation; *f f* are vents for conducting the mercurial vapors into two chambers *i*, separated by a triangular body of masonry *m n*; *h* is the smoke chimney of the fire-place; *o o*, are the ranges of aludels, in connexion with the chamber *i*, which are laid slantingly towards the gutter *g*, upon the double inclined plane terrace, and terminate in the chamber *h q*; this being surmounted by two chimneys *t*. The mercury is collected in these aludels and in the basins at *q* and *p*, *fig. 894*. *r* is a thin stone partition set up between the two principal walls of each of the furnaces. *v* is the stair of the aludel terrace, leading to the platform which surmounts the furnace; *z* is a gutter for conducting away the rains which may fall upon the buildings.

Great apparatus of Idria.—Before entering into details of this laboratory, it will not be useless to recapitulate the metallurgic classification of the ores treated in it. 1. the ores in large blocks, fragments, or shivers, whose size varies from a cubic foot to that of a nut. 2. The smaller ores, from the size of a nut to that of grains of dust.

The first class of large ores comprises three subdivisions, namely; *a*, blocks of metaliferous rocks, which is the most abundant and the poorest species of ore, affording only one per cent. of mercury; *b*, the massive sulphuret of mercury, the richest and rarest ore, yielding 80 per cent. when it is picked; *c*, the fragments or splinters proceeding from the breaking and sorting, and which vary in value, from 1 to 40 per cent.

The second class of small ores comprises: *d*, the fragments or shivers extracted from the mine in the state of little pieces, affording from 10 to 12 per cent.; *e*, the kernels of ore separated on the sieve, yielding 32 per cent.; *f* the sands and paste called *schlich*, obtained in the treatment of the poorest ores, by means of the stamps and washing tables; 100 parts of this *schlich* give at least 8 of quicksilver.

The general aspect of the apparatus is indicated by *figs. 896, 897, and 898*. *Fig. 898*,

represents the exterior, but only one half, which is enough, as it resembles exactly the other, which is not shown. In these three figures the following object may be distinguished; *figs. 896, 897*, *a*, door of the fire-place; *b*, the furnace in which beech-wood is burned mixed with a little fir-wood; *c*, door of the ash-pit, extended beneath; *d*, a space in which the ores are deposited upon the seven arches, 1 to 7, as indicated in *figs. 896, and 899*; *e e*, brick tunnels, by which the smoke of the fuel and the vapors of mercury pass, on the one side, into successive chambers *f k*.

f g h i j k l are passages which permit the circulation of the vapors from the furnace *a b c d*, to the chimneys *l l*. *Figs. 896 and 897* exhibit clearly the distribution of these

openings on each side of the same furnace, and in each half of the apparatus, which is double, as *fig. 897* shows; the spaces without letters being in every respect similar to the spaces mentioned below. *Fig. 897* is double the scale of *fig. 896*.

m m', *fig. 897*, are basins of reception, distributed before the doors of each of the chambers *f k f' k'*. The condensed mercury which flows out of the chambers is conveyed thither. *n n'* is a trench into which the mercury, after being lifted into the basins *m*, is poured, so that it may run towards a common chamber *o*, in the sloping direction indicated by the arrows. *o* leads to the chamber where the mercury is received into a porphyry trough; out of which it is laded and packed up in portions of 50 or 100 lbs. in sheep-skins prepared with alum. *p p'*, *fig. 896*, are vaulted arches, through which a circulation may go on round the furnace *a b c d*, on the ground level. *q q'* are the vaults of the upper stories. *r r'*, *fig. 898*, vaults which permit access to the tunnels *e' e''*, *fig. 896*.

s s' and *t t'*, *fig. 898*, are the doors of the chambers *f k* and *f' k'*. These openings are shut during the distillation by wooden doors faced with iron, and luted with a mortar of clay and lime. *u u'* is the door of the vaults 1 to 7 of the furnace represented in *fig. 896*. These openings are hermetically shut, like the preceding. *v v'*, *fig. 896*, are superior openings of the chambers, closed during the operation by luted plugs; they are opened afterwards to facilitate the cooling of the apparatus, and to collect the mercurial soot. *x y z*, *fig. 899*, are floors which correspond to the doors *u u'* of the vaults 1 to 7,

fig. 898. These floors are reached by stairs set up in the different parts of the building, which contains the whole apparatus.

On the lower arches the largest blocks of metalliferous rock are laid; over these the less bulky fragments are arranged, which are covered with the shivers and pieces of less dimension. On the middle vaults, the small ore is placed, distributed into cylindrical pipkins of earthenware, of 10 inches diameter and 5 inches depth. The upper vaults receive likewise pipkins filled with the sands and pastes called *schlich*.

In 3 hours, by the labor of 40 men, the two double sets of apparatus are charged, and all the apertures are closed. A quick fire of beech-wood is then kindled; and when the whole mass has become sufficiently heated, the sulphuret of mercury begins to vaporize; coming into contact with the portion of oxygen which had not been carbonated, by combustion, its sulphur burns into sulphurous acid, while the mercury becomes free, passes with the other vapors into the chambers for condensing it, and precipitates in the liquid form at a greater or less distance from the fire-place. The walls of the chambers and the floors, with which their lower portion is covered, are soon coated over with a black mercurial soot, which, being treated anew, furnishes 50 per cent. of mercury. The distillation lasts from 10 to 12 hours; during which time the whole furnace is kept at a cherry-red heat. A complete charge for the two double apparatus, consists of from 1000 to 1300 quintals of ore, which produce from 80 to 90 quintals of running mercury. The furnace takes from 5 to 6 days to cool, according to the state of the weather; and if to that period be added the time requisite for withdrawing the residuums, and attending to such repairs as the furnace may need, it is obvious that only one distillation can be performed in the course of a week.

In the works of Idria, in 1812, 56,686 quintals and a half of quicksilver ores were distilled, after undergoing a very careful mechanical preparation. They afforded 4832 quintals of running mercury; a quantity corresponding to about $8\frac{1}{2}$ per cent. of the ore. These smelting works are about 180 feet long and 30 feet high.

Upon the preceding three systems of smelting mercurial ores, I shall now make some observations.

It has been long well known, that quicksilver may be most readily extracted from cinnabar, by heating it in contact with quicklime. The sulphur of the cinnabar con-

bines, by virtue of a superior affinity with the lime, to the exclusion of the quicksilver, to form sulphurets of lime and calcium, both of which being fixed *heparis*, remain in the retort while the mercury is volatilized by the heat. In a few places, *hammerschlag*, or the iron cinder, driven off from the blooms by the tilting hammer, has been used instead of lime in the reduction of this mercurial ore, whereby sulphurous acid and sulphuret of iron are formed.

The annual production of the Bavarian Rhine provinces has been estimated at from 400 to 550 quintals; that of Almaden, in the year 1827, was 22,000 quintals; and of Idria, at present, is not more than 1500 quintals.

All the plans hitherto prescribed for distilling the ore along with quicklime, are remarkably rude. In that practised at Landsberg by Obermoschel, there is a great waste of labor, in charging the numerous small cucurbits; there is a great waste of fuel in the mode of heating them; a great waste of mercury by the imperfect luting of the retorts to the receivers, as well as the imperfect condensation of the mercurial vapors; and probably a considerable loss by pilfering.

The modes practised at Almaden and Idria are, in the greatest degree, barbarous; the ores being heated upon open arches, and the vapors attempted to be condensed by enclosing them within brick or stone and mortar walls, which can never be rendered either sufficiently tight or cool.

To obviate all these inconveniences and sources of loss, the proper chemical arrangements suited to the present improved state of the arts ought to be adopted, by which labor, fuel, and mercury, might all be economized to the utmost extent. The only apparatus fit to be employed is a series of cast-iron cylinder retorts, somewhat like those employed in the coal gas works, but with peculiarities suited to the condensation of the mercurial vapors. Into each of these retorts, supposed to be at least one foot square in area, and 7 feet long, 6 or 7 cwts. of a mixture of the ground ore with the quicklime, may be easily introduced, from a measured heap, by means of a shovel. The specific gravity of the cinnabar being more than 6 times that of water, a cubic foot of it will weigh more than $3\frac{1}{2}$ cwts.; but supposing the mixture of it with quicklime (when the ore does not contain the calcareous matter itself) to be only thrice the density of water, then four cubic feet might be put into each of the above retorts, and still leave $1\frac{1}{2}$ cubic feet of empty space for the expansion of volume which may take place in the decomposition. The ore should certainly be ground to a moderately fine powder, by stamps, iron cylinders, or an edge wheel, so that when mixed with quicklime, the cinnabar may be brought into intimate contact with its decomposer, otherwise much of it will be dissipated unproductively in fumes, for it is extremely volatile.

Figs. 900, 901, 902, represent a cheap and powerful apparatus which I contrived at the request of the German Mines Company of London, and which is now mounted at Landsberg, near Obermoschel, in the Bavarian Rhein-Kreis.

Fig. 900, is a section parallel to the front elevation of three arched benches of retorts,

900

of the size above specified. Each bench contains 3 retorts, of the form represented by *a a a*. *i*, is the single fire-place or furnace, capable of giving adequate ignition by coal or wood, to the three retorts. The retorts were built up in an excellent manner, by an English mason perfectly acquainted with the best modes of erecting coal-gas retorts, who was sent over on purpose. The path of the flame and smoke is precisely similar to that represented in fig. 670, page 847, whereby the uppermost retort is immersed in a bath of uniformly ignited air, while the currents reverberated from the top, play round the two undermost retorts, in their way to the vent-flues beneath

them. The bottom of the uppermost retort is protected from the direct impulse of the flame by fire-tiles. The dotted lines $\kappa \kappa$, show the paths of the chimneys which rise at the back ends of the retorts.

In the section, *fig. 901*, a is the body of the retort; its mouth at the right hand end is shut, as usual, by a luted iron lid, secured with a cross-bar and screw-bolts; its other end is prolonged by a sloping pipe of cast iron, 4 inches in diameter, furnished with a nozzle hole at z , closed with a screw plug.

Through this hole a wire rammer may be introduced, to ascertain that the tube is pervious, and to cleanse it from the mercurial soot, when thought necessary. c , is a cross section of the main condenser, shown in a longitudinal section at $c c$, *fig. 902*. This pipe is 18 inches in diameter, and about 20 feet long. At $a a$, &c., the back ends of the retorts are seen, with the slanting tubes $b b$, &c., descending through orifices in the upper surface of the condenser pipe, and dipping their ends just below the water-line $h i$. g , is the cap of a water valve, which removes all risk from sudden expansion or condensation. The

condenser is placed within a rectangular trough, made either of wood or stone, through which a sufficient stream of water passes to keep it perfectly cool, and repress every trace of mercurial vapor, and it is laid with a slight inclination from i to h , so that the condensed quicksilver may spontaneously flow along its bottom, and pass through the

vertical tube d into the locked up iron chest, or magazine e . This tube d is from the beginning closed at bottom, by immersion in a shallow iron cup, always filled with mercury. k is a graduated gauge rod, to indicate the progressive accumulation of quicksilver in the chest, without being under the necessity of unlocking it.

This air-tight apparatus was erected about a year ago, and has been found to act perfectly well; I regret, however, that my professional engagements at home have not hitherto permitted me to conduct its operations personally for some days. The average samples of cinnabar ore from Obermoschel are ten times poorer than those of Almaden. Were such an apparatus as the above, with some slight modifications which have lately occurred to me, mounted for the Spanish mines, I am confident that their produce in quicksilver might be nearly doubled, with a vast economy of fuel, labor, and human life. The whole cost of the 9 large retorts, with their condensing apparatus, iron magazine, &c., was very little more than *two hundred pounds*! As the retorts are kept in a state of nearly uniform ignition, like those of the gas works, neither they nor the furnaces are liable to be injured in their joints by the alternate contractions and expansions, which they would inevitably suffer if allowed to cool; and being always ready heated to the proper pitch for decomposing the mercurial ores, they are capable of working off a charge, under skilful management, in the course of 3 hours. Thus, in 24 hours, with a relay of laborers, 8 charges of at least 5 cwt. of ore each, might be smelted—2 tons, with 3 retorts, and 6 tons with 9 retorts; with a daily product from the rich ores of Almaden, or even Idria, of from 12 cwt. to 20 cwt. Instead of 3 benches of 3 retorts each, I would recommend 15 benches, containing 45 retorts, to be erected for either the Almaden or Idria mines; which, while they would smelt all their ores, could be got for a sum not much exceeding 1000*l.*, an outlay which they would reimburse within a month or two.

The following letter from Dr. Tobin gives an interesting account of the mercurial mines in California.

"That part of California where I have been residing, and that which I have just visited, consists of three long ranges of trapp mountains, with two wide valleys dividing them, the valley of the San Joaquin, and the valley of Santa Clara. Near this last place are the quicksilver mines of New Almaden, where I have been working. The matrix of the cinnabar ore is the same trapp of which the mountain ranges are composed, and as yet only one great deposit of this ore has been found, though *traces* of quicksilver ores have been discovered in other places. The ores are composed solely of sulphuret of mercury, (averaging 36 per cent.), red oxide of iron and silica; and had the mine been properly worked from the commencement almost any quantity of ore might be extracted; it now, however, more resembles a gigantic rabbit warren than a mine. The owners have lately sent out an old German miner, an experienced and practical man, who, if he stays here, will eventually put it into some kind of order. Its greatest depth is about 150 feet, and the weekly extraction of ores varies from 100 to 150 tons. Upon arriving here I found the concern in such a state of disorganization, that, after waiting three months in vain, and not having received a single cylinder or piece of machinery, I returned to Mexico to fetch up one of the proprietors. During my absence the former director, who in his life had never seen a mine, much less smelting works, put up four of the cylinders, supporting them solely upon their two ends without any fire-brick guards or pillars. Of course, when heated they sunk or sagged in the middle. Upon my return with one of the owners, something like order was established by him, and I got 16 cylinders at work, producing 1400 to 1500 lbs. daily. The result to me was satisfactory, but not so to the proprietor, on account of the expense of fuel and labor; he accordingly got a blacksmith, who had been sent here to put up the water-wheel, to build him a small furnace, without consulting me at all. This man sent a friend of his, not liking to come himself, to look at the plans I had of the furnaces of Idría and Almaden, and then erected a small and miserable furnace to hold one ton of ore, upon a *disimproved* plan of those of Idría. With this he obtained from the richest ores (65 to 72 per cent.) 38 per cent. of mercury, of course with the consumption of very little wood and with little labor; (the loss of per centage was not thought about!) The proprietor immediately determined to have six similar furnaces built, and with great regret allowed me to erect one good furnace, and afterwards a second one.

"Now take the results of the year's work, and you can judge whether the report sent you is true or not, that the Yankee blacksmith has superseded me or not. Before the year was half out, he got tired of attempting to compete with my furnaces, and left in disgust.

The cylinders produced	251,616 lbs. Mercury
(but were stopped in November on account of expense of working)	

The first furnace, working only from November 1st to July 1st, 1851, gave	620,513
The second furnace, working only from March 18th to July 1st, gave	383,825

Total 1,255,954

"The product of the Yankee's six furnaces, working for a much longer period, as they went into operation long before mine, was only 544,000 lbs., making a total product for the year of about 18,000 quintals."

Quicksilver is a substance of paramount value to science. Its great density and its regular rate of expansion and contraction by increase and diminution of temperature, give it the preference over all liquids for filling barometric and thermometric tubes. In chemistry it furnishes the only means of collecting and manipulating, in the pneumatic trough, such gaseous bodies as are condensable over water. To its aid, in this respect, the modern advancement of chemical discovery is pre-eminently due.

This metal alloyed with tin-foil forms the reflecting surface of looking-glasses, and by its ready solution of gold or silver, and subsequent dissipation by a moderate heat, it becomes the great instrument of the arts of gilding and silvering copper and brass. The same property makes it so available in extracting these precious metals from their ores. The anatomist applies it elegantly to distend and display the minuter vessels of the lymphatic system, and secretory systems, by injecting it with a syringe through all their convolutions. It is the basis of many very powerful medicines, at present probably too indiscriminately used, to the great detriment of English society; for it is far more sparingly prescribed by practitioners upon the continent of Europe, not otherwise superior in skill or science to those of Great Britain.

The nitrate of mercury is employed for the *secretage* of rabbit and hare-skins, that is, for communicating to fur of these and other quadrupeds the faculty of felting, which they do not naturally possess. With this view the solution of that salt is applied to them lightly in one direction with a sponge. A compound amalgam of zinc and tin is probably the best exciter which can be applied to the cushions of electrical machines.

The only mercurial compounds which are extensively used in the arts, are factitious cinnabar or VERMILION, and corrosive sublimate. Quantity imported for home consumption in 1850, 355,079 pounds; in 1851, 27,370 pounds.

A large quantity of mercury or quicksilver is annually produced in Idria, a town in the duchy of Carniola, the inhabitants of which are chiefly occupied in its extraction. The quicksilver mines are extremely productive. The cinnabar ore yields when very rich, 50 per cent. of this metal. This ore is a sulphuret of mercury, and gives up the latter metal by sublimation.

With the quicksilver mines of Idria is connected a manufactory of vermilion, which produced, in the year 1847, 981 cwt. of that pigment. The residue of the quicksilver is used up to some small extent, about 300 cwt., for technical purposes and preparations; but the greater portion of it is sent abroad. The exports of quicksilver amounted to an annual average of 2,341 cwt. (in the year 1846 they reached 5,478 cwt.), and of preparations derived from it, such as corrosive sublimate, calomel, &c., to 41 cwt. By the consumption of quicksilver, for the manufacture of vermilion and for other technical purposes, the value of the annual produce of the raw material is greatly increased. The mines have been worked for upwards of three centuries and a half, and were originally discovered by an accident.

MERCURY, BICHLORIDE OF; *Corrosive sublimate* (*Deutochlorure de mercure*, Fr.; *Aetzendes quicksilver sublimat*, Germ.), is made by subliming a mixture of equal parts of persulphate of mercury, prepared as above described, and sea-salt, in a stoneware cucurbit. The sublimate rises in vapor, and incrusts the globular glass capital with a white mass of small prismatic needles. Its specific gravity is 5.14. Its taste is acrid, styptometallic, and exceedingly unpleasant. It is soluble in 20 parts of water, at the ordinary temperature, and in its own weight of boiling water. It dissolves in $2\frac{1}{2}$ times its weight of cold alcohol. It is a very deadly poison. Raw white of egg swallowed in profusion, is the best antidote. A solution of corrosive sublimate has been long employed for preserving soft anatomical preparations. By this means the corpse of Colonel Morland was embalmed in order to be brought from the seat of war to Paris. His features remained unaltered, only his skin was brown, and his body was so hard as to sound like a piece of wood when struck with a hammer.

In the valuable work upon the dry rot, published by Mr. Knowles, secretary of the committee of inspectors of the navy, in 1821, corrosive sublimate is enumerated among the chemical substances which had been prescribed for preventing the dry rot in timber; and it is well known that Sir H. Davy had, several years before that date, used and recommended to the Admiralty and Navy Board, corrosive sublimate as an anti-dry rot application. It has been since extensively employed by a joint-stock company for the same purpose, under the title of Kyan's patent.

MERCURY, PROTOCHLORIDE OF; *Calomel*; (*Protochlorure de mercure*, Fr.; *Versüßtes quicksilver*, Germ.) This compound, so much used and abused by medical practitioners, is commonly prepared by triturating four parts of corrosive sublimate along with three parts of running quicksilver in a marble mortar, till the metallic globules entirely disappear, with the production of a black powder, which is to be put into a glass balloon, and exposed to a subliming heat in a sand bath. The calomel, which rises in vapor, and attaches itself in a crystalline crust to the upper hemisphere of the balloon, is to be detached, reduced to a fine powder, or levigated and elutriated. 200 lbs. of mercury yield 236 of calomel and 272 of corrosive sublimate.

The following more economical process is that adopted at the Apothecaries' Hall, London. 140 pounds of concentrated sulphuric acid are boiled in a cast iron pot upon 100 pounds of mercury, till a dry persulphate is obtained. Of this salt, 124 pounds are triturated with 81 pounds of mercury, till the globules disappear, and till a protosulphate be formed. This is to be intimately mixed with 68 pounds of sea-salt, and the mixture, being put into a large stone-ware cucurbit, is to be submitted to a subliming heat. See CALOMEL.

From 190 to 200 pounds of calomel rise in a crystalline cake, as in the former process, into the capital; while sulphate of soda remains at the bottom of the alembic. The calomel must be ground to an impalpable powder, and elutriated. The vapors, instead of being condensed into a cake within the top of the globe or in a capital, may be allowed to diffuse themselves into a close vessel, containing water in a state of ebullition, whereby the calomel is obtained at once in the form of a washed impalpable powder. Calomel is tasteless and insoluble in water. Its specific gravity is 7.176.

For the compound of mercury with fulminic acid, see FULMINATE. *Periodide of mercury* is a bright but fugitive red pigment. It is easily prepared by dropping a solution of iodide of potassium into a solution of corrosive sublimate, as long as any precipitation takes place, decanting off the supernatant muriate of potash, washing and drying the precipitate.

MERCURY; new test for, by Mr. Morgan of Dublin. If a strong solution of iodide of potassium be added to a minute portion of any of the salts of mercury, placed on a

bright clean plate of copper, the mercury is immediately deposited in the metallic state, as a silvery stain upon the copper. No other metal is separated by like means. By this method corrosive sublimate may be detected in a drop of solution unaffected either by caustic potash or iodide of potassium. In a mixture of calomel and sugar, in the proportion of one grain to 200, a distinct metallic stain will be obtained with one grain, which of course contains $\frac{1}{320}$ of a grain of calomel. In like manner $\frac{1}{160}$ of a grain of peroxide of mercury may be detected, although the mixture with sugar is not in the least colored by it. With the preparations of mercury in the undiluted state, this process acts with remarkable accuracy, the smallest quantity of calomel or peroxide, placed on copper as above, will give with iodide of potassium a distinct metallic stain. Mr. Morgan supposes that the iodide of potassium forms a soluble salt with the several salts of mercury, which is easily decomposed.—*Ph. Journ.*, Feb. 1852.

METALLIC ANALYSIS. Professor Liebig has lately enriched this most useful department of practical chemistry, by the employment of the cyanide of potassium prepared in his economical method (see this article). This salt is the best reagent for detecting nickel in cobalt. The solution of the two metals being acidulated, the cyanide is to be added until the precipitate that first falls is redissolved. Dilute sulphuric acid is then added, and the mixture being warmed and left in repose, a precipitate does not fail to appear sooner or later, which is a compound of nickel. Cyanide of potassium serves well to separate lead, bismuth, cadmium, and copper, four metals often associated in ores. On adding the cyanide in excess to the solution of these metals in nitric acid, lead and bismuth fall as carbonates, and may be parted from each other by sulphuric acid. Sulphuretted hydrogen is passed in excess through the residuary solution, and the mixture being heated, a small quantity of cyanide is added: a yellow precipitate indicates cadmium; and a black precipitate falls on the addition of hydrochloric acid, if copper be present.

If into a crucible (containing the cyanide fused by heat), a little of any metallic oxide be thrown at intervals, it will be almost immediately reduced to the reguline state. When the fluid mass is afterward decanted, the metal will be found mixed with the white saline matter, from which it may be separated by water.

Even metallic sulphurets are reduced to the state of pure metals by being projected in a state of fine powder into the fused cyanide. When an iron ore is thus introduced, along with carbonate of potash or soda, and the mixture is heated to fusion, which requires a strong red heat, the alumina and silica of the ore fuse into a slag; from which, on cooling, the metallic iron may be separated by the action of water, and then weighed. If manganese exist in the ore, it remains in the state of protoxide; to be determined by a separate process. When oxide of copper is sprinkled on the surface of the fused cyanide, it is immediately reduced, with the disengagement of heat and light. The mixture being poured out of the crucible and concentered, is to be ground and washed, when a pure regulus of copper will be obtained.

The process of reduction is peculiarly interesting with the oxide of antimony and tin; being accomplished at a low red heat, hardly visible in daylight. Even the sulphurets of these metals are immediately stripped of their sulphur, with the formation of sulphocyanide of potassium.

Cyanide of potassium, mixed with carbonate of soda, is an excellent re-agent in blow-pipe operations for distinguishing metals. The reductions take place with the utmost facility, and the fused mixture does not sink into the charcoal, as carbonate of soda alone is apt to do in such cases. Hence the grains or beads of metal are more visible, and can be better examined.

When the cyanide is heated along with the nitrates and chlorates (of potash), it causes a rapid decomposition, accompanied with light and explosions.

Arsenic may be readily detected in the commercial sulphuret of antimony, by fusing it with three fourths of its weight of the cyanide in a porcelain crucible over a spirit lamp, when a regulus of antimony is obtained. The metal may then be easily tested for arsenic; since none of this volatile substance can have been lost, owing to the low temperature employed.

When arsenious acid, or orpiment, or any of the arseniates, are mixed with six times their weight of the mixture of cyanide and carbonate of soda in a tube with a bulb at one end, and heat applied with a spirit lamp to the glass, very beautiful rings of metallic mirror are formed by the reduced arsenic. The arseniates of lead and peroxide of iron, however, do not answer to this test.

When sulphates of lead and barytes, along with silica, are mixed with four or five times their weight of the above mixed cyanide and carbonate, and fused, the sulphate of lead is reduced to the metallic state, the sulphate of barytes becomes a carbonate, and the silica gets combined with the alkali into a soluble glass.

METALLIC FUMES (CONDENSATION OF), by the Duke of Buccleugh.—In all great smelting works of lead and copper, the smoke rising from the furnaces is highly charged with the most noxious vapors, containing, besides other poisonous matter, a

large quantity of lead. Many attempts have been made to obviate this nuisance; and the system adopted by the exhibitor has been found to be very successful.

An oblong building in solid masonry, about 30 feet in height, is divided by a partition wall into two chambers, having a tall chimney or tower adjoining, which communicates with one of the chambers at the bottom. The smoke from the various furnaces, eight in number, and about 100 yards distance from the condenser, is carried by separate flues into a large chamber; from thence by a larger flue it enters the first chamber of the condenser at the very bottom, and is forced upwards in a zigzag course towards the top, passing four times through a shower of water constantly percolating from a pierced reservoir at the summit of the tower. The smoke is again compelled to filter a fifth time, through a cube of coke, some 2 feet square, through which a stream of water filters downwards, and which is confined to its proper limits by a vertical grating of wood. The smoke having reached the top, is now opposite the passage into the second or vacuum chamber.

This is termed the exhausting chamber, and is above 5 feet by 7 feet inside, and 30 or more feet in height. On its summit is fixed a large reservoir, supplied by an ample stream of water, always maintaining a depth of 6 to 10 inches.

The bottom of this tank is of iron, having several openings or slots, 12 in number, about an inch in width, and extending across the whole area of the reservoir, communicating directly with the chamber beneath. On this iron plate works a hydraulic slide plate, with openings corresponding in one position with those in the reservoir.

This plate receives a horizontal reciprocating motion from a water-wheel or other power, driven by means of a connecting-rod and crank.

In the middle of every stroke, the openings in the plate correspond with those in the bottom of the reservoir, and a powerful body of water falls as a shower-bath the whole height of the vacuum chamber; and, in doing so, sweeps the entire inside area, carrying with it every particle of insoluble matter, held suspended in the vapors coming from the furnaces.

The atmospheric pressure, of course, acts in alternate strokes as a blast at the furnace mouths, and causes a draft sufficiently strong to force the impure vapors through the various channels in connection with the water, the wet coke and exhausting chambers, until it passes, purified and inert, into the open atmosphere.

The water saturated with particles of lead, &c., held in mechanical solution, finally passes into great dykes or reservoirs excavated for the purpose; and then deposits at leisure its rich charge of metal.

Formerly the noxious fumes passing from the shafts of the furnaces poisoned the neighborhood; the heather was burnt up, vegetation destroyed, and no animal could graze or bird feed near the spot.

Now, the green heather is seen in all its native luxuriance close around the establishment; and the sheep graze within a stone's throw of the chimney's base, and game on all sides take shelter.

METALLIC STATISTICS. The county of Cornwall is the most important mineral district of the United Kingdom for the number of its metalliferous minerals, many of which are not found in any other part of our islands. At a very early period of our history, mines were worked around the sea-coasts of Cornwall, of which the evidences are still to be seen at Tol-pedden-Penwith, near the Land's End; in Gwennap, near Truro; and at Cadgwith, near the Lizard Point. The traditional statements that the Phœnicians traded for tin with the Britons in Cornwall are very fairly supported by corroborative facts; and it is not improbable that the *Ictes* or *Iktis* of the ancients was St. Michael's Mount, near Penzance.

In the reign of King John, the mines of the western portion of England appear to have been principally in the hands of the Jews. The modes of working must have been very crude, and their metallurgical processes exceedingly rough. From time to time the remains of furnaces, called Jew's houses, have been discovered, and small blocks of tin, known as Jew's tin, have not unfrequently been found in the mining localities.

Till a comparatively recent date, tin was the only metal which was sought for; and, in many cases, the mines were abandoned when the miners came to the yellows, that is, the yellow sulphuret of copper. The greatest quantity of tin has been produced by streaming (as washing the debris in the valleys is termed); and this variety, called stream tin, produces the highest price in the market.

The conditions under which these deposits occur are curious and instructive. At the Carnon Tin Stream Works, north of Falmouth, the rounded pebbles of tin are found at a depth of about 50 feet from the surface, beneath the bottom of an estuary, where trees are discovered in their places of growth, together with human skulls, and the remains of deer, amidst the vegetable accumulations which immediately cover the stanniferous beds. According to Mr. Henwood's measurement, the section presents first about 50 feet of silt and gravel; then a bed of 18 inches in thickness of wood, leaves, nuts, &c., resting on the tin ground, composed of the debris of quartz, slate, and granite, and the

tin ore. At the Pentuan Works, near St. Austell, similar deposits occur, proving a material alteration in the level during the period expended in the formation of this deposit. Tin is also worked out of the lode in many parts, the ore occurring both in the slate and the granite formations. The modes of dressing the tin ore, preparing it for the smelter, and the process of smelting, are illustrated in the Exhibition.

There has been a remarkable uniformity in the quantity of tin produced in Cornwall during a long period, as will be seen from the following table:—

Years.	Tons.	Price per cwt.	
		£	s.
1750	1,600		
1760	1,800		
1770	2,000		
1780	1,800	3	0
1790	2,000	3	15
1800	1,600	5	0
1810	1,400	7	0
1820	1,700	3	5
1830	3,500	3	0
1840	5,000	3	15

The produce of this metal within the last few years has been as follows:—

Years.	Tons.
1844	7,507
1845	7,739
1846	8,945
1847	10,072
1848	10,176
1849	10,719

The produce of zinc is not easily attainable, but it is now somewhat considerable, as is also that of arsenic, and of the iron pyrites, used in the manufacture of sulphuric acid.

The number of individuals employed in 59 Cornish copper mines was computed by Sir Charles Lemon in 1837, to be—

Men	-	-	-	10,624
Women	-	-	-	3,802
Children	-	-	-	3,490

The men alone work underground; the women and children are employed on the surface picking and dressing the ore.

Mr. W. Henwood estimates the number employed at—

Men	-	-	-	18,472
Women	-	-	-	5,764
Children	-	-	-	5,764

30,000

Tin appears to have been raised in Cornwall from a very early period. Traditionary evidence, supported by strong corroborative facts, appears to prove that the kingdoms around the Mediterranean Sea were supplied with tin from Cornwall by the Phœnician merchants at a very early date. The circumstance of this metal being found in the beds of streams, and in deposits at the base of the primary rocks, from which it could be obtained without much labor, may have been the cause of its being early known to the Britons.

The oxide of tin is usually found deposited in beds in water-worn pebbles, and mixed with the débris of the neighboring hills. There can be but little doubt that these tin deposits are the result of the disintegrating action of the atmospheric causes and of water. Some of the tin beds, 30 or 50 feet from the present surface, contain vegetable matter, as branches of trees and large logs of wood; and at Carnon Stream Works, human skulls were discovered amidst the débris, 53 feet below the surface. Tin is also found in the lode, either as peroxide, cupreous-sulphuret of tin, or tin pyrites, the analysis of the peroxide giving peroxide of tin, 96.265; silica, 0.750; peroxide of iron and manganese, 3.395.

Many indications of early tin-mining are to be found in Cornwall, as stated in preceding note. For many centuries the Duke of Cornwall drew a large revenue from its tin. The tin, when smelted into blocks, was forwarded to the nearest coinage town, there to be stamped by the duchy officers, who cut a piece of the corner of each block, *which was retained as the duchy's dues.* In 1337, Edward the Black Prince was created Duke of Cornwall, and then the average profit of the coinage was 4,000 marks

per annum. In 1814, the revenues to the duchy from tin was about 8,500*l.*, and the average tin revenue from 1820 to the abolition of the coinages in October, 1838, has been estimated at 12,000*l.* per annum. In 1750, about 2,000 tons of tin were produced in Cornwall, and in 1838, about 5,000. Since that period the quantity can be accurately ascertained, the trade in tin being in the hands of a few, and the purchases of ore being usually made by private contract.

By the returns to five several orders made by the House of Commons, which were obtained by the exertions and perseverance of Sir J. J. Guest, Sir C. Lemon, and Mr. Evans (M. P. for North Derbyshire), we are enabled to lay before our readers a most correct account of the various exports and imports of iron and iron ore, hardware, cutlery, &c., copper ore, tin, zinc, lead ore, and lead, for the year ending Jan. 5, 1844.

Commencing with iron, it appears there was imported in the year, iron ore, 131 tons; chromate of iron, 1393 tons; pig-iron, 243 tons; unwrought iron in bars, 12,795 tons; bloom, 563 tons; rod-iron, 12 tons; old, broken, and cast-iron, 286 tons; cast-iron, only 8 tons; steel, unwrought, 1697 tons—of these, 97 tons only were entered by weight, the remainder by value, 11035*l.* 6*s.* 9*d.* Of the several countries from which these importations came, the principal is Sweden, whence we have received of iron 10,909 tons, and steel 1558 tons, leaving but a small portion to divide between twenty other places. Our exports of foreign iron have been, unwrought, in bars, 3986 tons; rod, 10 tons; hoops, 2 tons; cast-iron, 11 cwt.; steel, unwrought, 1456 tons. The total quantity of foreign iron retained for home consumption was 14,782 tons, upon which the net amount of duty was 14,563*l.* The exportation of that staple produce of our own country, British iron, was as follows:—Bar-iron, 176,148 tons; bolt and rod, 22,625 tons; pig-iron, 154,770 tons; cast-iron, 18,449 tons; iron wire, 1508 tons; wrought-iron, consisting of anchors, grapnels, &c., 3058 tons; hoops, 14,591 tons; nails, 6020 tons; and all other sorts, except ordnance, 44,577 tons; old iron for manufacture, 5924 tons; and unwrought steel, 3199 tons. Those places which have taken the greatest portions of this produce are—Russia, 10,963 tons of bar-iron; Denmark, 10,447 tons bar, and 7010 tons pig; Prussia, 12,009 tons bar, 17,480 tons pig; Germany, 13,298 tons bar, 6322 tons pig, 1339 tons cast; Holland, 17,509 tons bar, 75,953 tons pig; 4317 tons cast; Belgium, 4270 tons cast; France, 4237 tons bar, 22,103 tons pig; Italy, 21,930 tons bar, 3982 tons bolt and rod, 3005 tons pig; Turkey, and Continental Greece, 6412 tons bar; East Indies and Ceylon, 20,620 tons bar, 2967 tons bolt; British North American Colonies, 6887 tons bar, 1995 tons cast; Foreign West Indies, 5043 tons bar, 1646 tons cast; and to the United States, 21,336 tons bar, and 7148 tons pig. The largest quantity of unwrought steel has been to the latter place—viz. 1335 tons.

Of British hardware and cutlery, we exported in the year 17,183 tons, valued at 1,745,518*l.*; the principal of which has been—to Germany, 1237 tons, value 159,889*l.*; East Indies, 1402 tons, value 142,607*l.*; British North American Colonies, 1129 tons, value 102,260*l.*; British West Indies, 997 tons, value 80,040*l.*; Foreign West Indies, 657 tons, value 48,609*l.*; United States, 4282 tons, value 448,341*l.*; Brazil, 943 tons, value, 80,070*l.*; and divers other places, varying from 100 to 500 tons.

We now come to copper. Of foreign copper ores, we have imported 55,720 tons, and of metallic copper, unwrought and wrought plates, and coins, 805 tons. Of the ores, the greatest quantities have come from Cuba and Chili.

We have exported 1819 tons of British, and 650 tons of foreign tin—of which France has taken 626 tons, Russia 480 tons, Italy 183 tons, Turkey 250 tons, and the remainder distributed among twenty-seven places.

Of foreign zinc, we have imported as follows:—

Countries from whence imported.	Tons.	Cwt.	Qrs.	Lbs.
Denmark	268	19	2	21
Prussia	6860	15	3	22
Germany	3000	1	2	11
Holland	20	3	2	1
Belgium	21	9	0	9
Syria and Palestine	1	15	0	15

Total import of foreign zinc Tons 10,173 4 3 23

Of this, we retained for home consumption 4102 tons, on which the nett duty was 223*l.* 2*s.* 10*d.*; and we have exported 1895 tons of British, and 6445 tons of foreign spelter.

Of foreign lead, we have imported 2863 tons—of which 2775 tons were pig and sheet, 68 tons ore, and 19 tons white lead; 157 tons were retained for home consumption, on which the duty was 165*l.*; and we imported from the Isle of Man, duty free, 2415 tons of lead ore. Our exportation of foreign lead amounted to 2439 tons—while of British, we exported, 176 tons of ore, 14,610 tons pig and sheet, 378 tons litharge, 707 tons red lead, and 1224 tons white lead—making a total of 17,991 tons.—*Railway and Commercial Gazette*, May 18, 1844.

An Account of Sales, by Public Ticketing, of the British and Foreign Copper Ores in Cornwall and Swansea, from the 30th of June, 1832, to the 30th of June, 1849, showing the Averages of the per Centage of Produce in Metal Prices, computed Quantities of Fine Copper, with General Averages, Total Produce in Metal, and Money Value of the whole. Also giving the Value of Ore computed to produce a Ton of Copper.

NOTE.—The four quantities in 1848 and 1849, marked with an asterisk, are not given as correct. The previous figures in the table may be relied upon. Those standing against 1849, being even sums, will be understood to be matter of computation. It is certain, however, that considerable parcels, especially of foreign ores, were purchased by private contract or imported; and the quantities here given may be regarded as quite below the amounts so purchased.

Quantities of Copper Ore imported from Chili, which paid Duty, in the Five Years 1843 to 1847 inclusive.

Totals.	240,515	55,710	21.88	299,813	1 3 6	5 5 4	88 17 0	5.927

Note.—The amount for 1848 has been presented to Parliament monthly; a statement which, with the annual returns, is introduced in another place. Since the passing of the Act of 1843, admitting the foreign ores at a nominal duty without regard to produce, the details furnished in the tables annexed to this have not been continued.

Imports of Foreign Copper and Copper Ore into the United Kingdom from 1832 to 1849, inclusive.

<i>ISLE OF MAN.</i>	2,021	1,665
Making a Total of	78,964	54,853

Lead Ore and Lead imported and exported during 1848.

Imported.—1,295 tons of lead ore; pig and sheet lead, 3,788 tons: retained for home consumption, 2,151 tons.

Exported.—135 tons of lead ore; pig and rolled lead, 4,977 tons; shot, 1,151 tons; litharge, red and white lead, 2,292 tons; foreign lead, in sheet and pig, 3,747 tons.

The Welsh sales include also the following lead ores:—Australian, 69 tons; Belgian, 85 tons; German, 44 tons; Portugal, 79 tons; Prussian, 112 tons; Sardinian, 112 tons.

The total amount of lead ore raised and sold in the United Kingdom, for the year 1848, was 78,964 tons, and metallic lead sold 54,853 tons; while in 1847, the amount of lead ore was 79,311 tons, and lead 53,410 tons—showing a decrease in the quantity of ore in 1848, as compared with a former year, of 347 tons, but an increase in the metal of 1,443 tons.

The price of English pig at the close of 1847 was 17*l.* 10*s.* per ton, and at the same period of 1848, 15*l.* 12*s.* per ton. A comparison of the two years thus shows no very great fluctuation in home trade; but, on referring to the imports and exports, we find a great increase in the latter year. The imports of lead ore in 1847 were 567 tons, and pig and sheet lead 394 tons; and the exports 86 tons of ore, and 3,435 tons of metal: while in 1848 the imports were 1,295 tons of ore, and 3,788 tons of metal; and the exports 135 tons of ore, and 6,128 tons of metal—showing an increase in the imports of 791 tons of ore, and 3,894 tons of metal; and in the exports of 49 tons of ore, and 2,693 tons of pig, sheet lead, and shot, and exclusive of manufactured metal in the shape of litharge and red and white lead.

Public sales of Tin Mines in the Counties of Cornwall and Devon, recorded in the Official Returns for the Year ending the 31st of December, 1849.

The whole produce of Tin Mines in the Counties of Cornwall and Devon must not be estimated by the above returns, inasmuch that such only relates to the public sales, to which we have access of information, while the greater portion is disposed of by private contract. Since the repeal of the embargo duty in 1838, it has been found impracticable to obtain any accurate return, and hence the imperfect table herewith presented.

CORNISH COPPER ORES.

Annual average Produce, Price, and Standard for Nine Years, from 1841 to 1849, inclusive, of Copper Ores sold at Cornish Ticketing, with the highest and lowest Prices of Cake Copper in each Year.

Year.	Standard.			Produce.	Price.			Cake Copper—per Ton.

The total amount of exports shows—in 1846, £3,298,026½; in 1847, £1,227,060½; in 1848, £5,597,790½; in 1849, £3,946,325½; and in 1850, £3,843,042½.

METALLURGY (*Erzkunde*, Germ.) is the art of extracting metals from their ores. This art, which supplies industry with the instruments most essential to its wants, is alike dependant upon the sciences of chemistry and mechanics; upon the former, as directing the smelting processes, best adapted to disentangle each metal from its mineralizer; upon the latter, as furnishing the means of grinding the ores, and separating the light stony parts from the rich metallic matter.

Notwithstanding the striking analogy which exists between common chemical and metallurgic operations, since both are employed to insulate certain bodies from others, there are essential differences which should be carefully noted. In the first place, the quantity of materials being always very great in metallurgy, requires corresponding adaptations of apparatus, and often produces peculiar phenomena; in the second place, the agents to be employed for treating great masses, must be selected with a view to economy, as well as to chemical action. In analytical chemistry, the main object being exactness of result, and purity of product, little attention is bestowed upon the value of the reagents, on account of the small quantity required for any particular process. But in smelting metals upon the great scale, profit being the sole object, cheap materials and easy operations alone are admissible.

The metallic ores as presented by nature, are almost always mixed with a considerable number of foreign substances; and could not therefore be advantageously submitted to metallurgic operations, till they are purified and concentrated to a certain degree by various methods.

OF THE PREPARATION OF ORES FOR THE SMELTING HOUSE.

There are two kinds of *preparation*; the one termed mechanical, from the means employed, and the results obtained, consists in processes for breaking and grinding the ores, and for washing them so as to separate the vein-stones, gangues, or other mixed earthy matters, in order to insulate or concentrate the metallic parts.

Another kind of preparation, called chemical, has for its object to separate, by means of fire, various volatile substances combined in the ores, and which it is requisite to clear away, at least in a certain degree, before trying to extract the metals they may contain.

Lastly, an indispensable operation in several circumstances, is to discover, by simple and cheap methods, called *assays*, the quantity of metal contained in the different species of ores to be treated.

This head of our subject, therefore, falls under three subdivisions:—

§ 1. The mechanical preparation of ores, including *picking*, *stamping*, and different modes of washing.

§ 2. The chemical preparation, consisting especially in the roasting or calcination of the ores.

§ 3. The assay of ores, comprehending the mechanical part: that is, by washing; the chemical part, or assays by the *dry way*; and the assays by the *moist way*.

Section 1. Of the mechanical preparation or dressing of ores.—1. The first picking or sorting takes place in the interior, or underground workings, and consists in separating the fragments of rocks, that apparently contain no metallic matter, from those that contain more or less of it. The external aspect guides this separation; as also the feeling of density in the hand.

The substances, when turned out to the day, undergo another *sorting*, with greater or less care, according to the value of the included metal. This operation consists in breaking the lumps of ore with the hammer, into fragments of greater or less size, usually as large as the fist, whereby all the pieces may be picked out and thrown away that contain no metal, and even such as contain too little to be smelted with advantage. There is, for the most part, a building erected near the output of the mine, in which the breaking and picking of the ores are performed. In a covered gallery, or under a shed, banks of earth are thrown up, and divided into separate beds, on each of which a thick plate of cast iron is laid. On this plate, elderly workmen, women, and children, break the ores with hand hammers, then pick and sort them piece by piece. The matters so treated, are usually separated into three parts; 1. the rock or sterile gangue, which is thrown away; 2. the ore for the stamping mill, which presents too intimate a mixture of rock and metallic substance to admit of separation by breaking and picking; and 3. the pure ore, or at least the very rich portion, called the *sorted mine* or the *fat ore*. On the sorting floors there remains much small rubbish, which might form a fourth subdivision of ore, since it is treated in a peculiar manner, by sifting, as will be presently mentioned.

The distribution of fragments more or less rich, in one class or another, is relative to the value of the included metal, taking into account the expenses necessary for its extraction.

Thus in certain lead mines, pieces of the gangues are thrown away, which judged by the eye may contain 3 per cent. of galena, because it is known that the greater portion of this would be lost in the washings required for separating the 97 parts of the gangue, and that the remainder would not pay the expenses.

II. The very simple operations of *picking* are common to almost all ores; but there are other operations requiring more skill, care, and expense, which are employed in their final state of perfection only upon ores of metals possessing a certain value, as those of lead, silver, &c. We allude to the *washing* of ores.

The most simple and economical washings are those that certain iron ores, particularly the alluvial, are subjected to, as they are found near the surface of the ground agglutinated in great or little pieces. It is often useful to clean these pieces, in order to pick out the earthy lumps, which would be altogether injurious in the furnaces.

This crude washing is performed sometimes by men stirring in the midst of a stream of water, with iron rakes or shovels, the lumps of ore placed in large chests, or basins of wood or iron.

In other situations, this washing is executed more economically by a machine called a *buddle* or *dolly-tub* by our miners. A trough of wood or iron, with a concave bottom, is filled with the ore to be washed. Within the tub or trough, arms or iron handles are moved round about, being attached to the arbor of a hydraulic wheel. The trough is kept always full of water, which as it is renewed carries off the earthy matters, diffused through it by the motion of the machine, and the friction among the pieces of the ore. When the washing is finished, a door in one of the sides of the trough is opened, and the current removes the ore into a more spacious basin, where it is subjected to a kind of *picking*. It is frequently indeed passed through sieves in different modes. See LEAD and TIN, for figures of *buddles* and *dollies*.

III. *Stamping*. Before describing the refined methods of washing the more valuable ores of copper, silver, lead, &c., it is proper to point out the means of reducing them into a powder of greater or less fineness, by *stamping*, so called from the name *stamps* of the pestles employed for that purpose. Its usefulness is not restricted to preparing the ores; for it is employed in almost every smelting house for pounding clays, charcoal, scoriae, &c. A stamping mill or pounding machine, fig. 903 consists of several

moveable pillars of wood *l l l*, placed vertically, and supported in this position between frames of carpentry *k k k*. These pieces are each armed at their under end with a mass of iron *m*. An arbor or axle *a*, moved by water, and turning horizontally, tosses up these wooden pestles, by means of wipers or cams, which lay hold of the shoulders of the pestles at *l l l*. These are raised in succession, and fall into an ob-

long trough below *m m*, scooped out in the ground, having its bottom covered either with plates of iron or hard stones. In this trough, beneath these pestles, the ore to be stamped is allowed to fall from a hopper above, which is kept constantly full.

The trough is closed in at the sides by two partitions, and includes three or four pestles; which the French miners call a *battery*. They are so disposed that their ascent and descent take place at equal intervals of time.

Usually a stamping machine is composed of several batteries (two, three, or four), and the arrangement of the wipers on the arbor of the hydraulic wheel is such that there is constantly a like number of pestles lifted at a time; a circumstance important for maintaining the uniform going of the machine.

The matters that are not to be exposed to subsequent washing are stamped dry, that is, without leading water into the trough; and the same thing is sometimes done with the rich ores, whose lighter parts might otherwise be lost.

Most usually, especially for ores of lead, silver, copper, &c., the trough of the stamper is placed in the middle of a current of water, of greater or less force; which, sweeping off the pounded substances, deposits them at a greater or less distance onwards, in the order of the size and richness of the grain; constituting a first washing, as they escape from beneath the pestles.

In the dry stamping, the fineness of the powder depends on the weight of the pestles, the height of their fall, and the period of their action upon the ore; but in the stampers exposed to a stream of water, the retention of the matters in the trough is longer or shorter, according to the facility given for their escape. Sometimes these matters flow out of the chest over its edges, and the height of the line they must surmount has an influence on the size of the grain; at other times, the water and the pounded matter

which it carries off, are made to pass through a grating, causing a kind of sifting at the same time. There are, however, some differences in the results of these two methods. Lastly, the quantity of water that traverses the trough, as well as its velocity, has an influence on the discharge of the pounded matters, and consequently on the products of the stampers.

The size of the particles of the pounded ore being different, according to the variable hardness of the matters which compose them, suggests the means of classing them, and distributing them nearly in the order of their size and specific gravity, by making the water, as it escapes from the stamping trough, circulate in a system of canals called a *labyrinth*, where it deposits successively, in proportion as it loses its velocity, the earthy and metallic matters it had floated along. These metalliferous portions, especially when they have a great specific gravity like galena, would be deposited in the first passages, were it not that from their hardness being inferior to that of the *gangue*, they are reduced to a much finer powder, or into thin plates, which seem to adhere to both the watery and earthy particles; whence they have to be sought for among the finest portions of the pulverized *gangue*, called *slime*, *schlich*, or *schlamme*.

There are several methods of conducting the stamps; in reference to the size of the grains wished to be obtained, and which is previously determined agreeably to the nature of the ore, and of the *gangue*; its richness, &c. The height of the slit that lets the pounded matters escape, or the diameters of the holes in the grating, their distance, the quantity of water flowing in, its velocity, &c., modify the result of the stamping operation.

When it is requisite to obtain powder of an extreme fineness, as for ores that are to be subjected to the process of amalgamation, they are passed under millstones, as in common corn mills; and after grinding, they are bolted so as to form a species of flour; or they are crushed between rolls. See LEAD and TIN.

Washing of ores.

IV. The ores pounded under the stamps are next exposed to very delicate operations both tedious and costly, which are called the *washings*. Their purpose is to separate mechanically the earthy matters from the metallic portion, which must therefore have a much higher specific gravity; for otherwise, the washing would be impracticable.

The medium employed to diminish the difference of specific gravity, and to move the lightest matters, is water; which is made to flow with greater or less velocity, in abundance over the *schlich* or pasty mud spread on a table of various inclination.

But as this operation always occasions, not only considerable expense, but a loss of metal, it is right to calculate what is the degree of richness below which water is unprofitable; and on the other hand, what is the degree of purification of the *schlich* which it is proper to stop, because too much metal would be lost comparatively with the expense of fusing a small additional quantity of *gangue*. There cannot, indeed, be a fixed rule in this respect, since the elements of these calculations vary for every work.

Before describing the different modes of washing, we must treat of the sifting or riddling, whose purpose, like that of the labyrinth succeeding the stamps, is to distribute and to separate the ores (which have not passed through the water stamps) in the order of the coarseness of grain. This operation is practised particularly upon the debris of the mine, and the rubbish produced in breaking the ores. These substances are put into a riddle, or species of round or square sieve, whose bottom is formed of a grating of a plate of metal pierced with holes. This riddle is plunged suddenly and repeatedly into a tub or cistern filled with water. This liquid enters through the bottom, raises the mineral particles, separates them and keeps them suspended for an instant, whence they fall down in nearly the order of their specific gravities, and are thus classed with a certain degree of regularity. The sieve is sometimes dipped by the immediate effort of the washer; sometimes it is suspended to a swing which the workman moves in order that the riddling may be rightly done, the sieve should receive but a slight movement from below upwards; in this case the ore is separated from the *gangue*; if there be different specific gravities, there are formed in the sieve as many distinct layers, which the workman can easily take out with a *spatula*, throwing the upper part into a tub when it is too poor to be re-sifted. This operation by the hand-sieve, is called *riddling in the tub*, or riddling by deposit.

We may observe, that during the sifting, the particles which can pass across the bottom of the tub, fall into the tub and settle down there; whence they are afterwards raised out, and exposed to washing when they are worth the trouble.

Sometimes, as at Poullaouen, the sieves are conical, and held by means of two handles by a workman; and instead of receiving a single movement, as in the preceding method, the sifter himself gives them a variety of dexterous movements in succession. His object is to separate the poor portions of the ore from the richer; in order to subject the latter to the stamp mill.

Among the siftings and washings which ores are made to undergo, we must not

among the most useful and ingenious, those practised by *iron gratings*, called on the Continent *grilles anglaises*, and the *step-washings* of Hungary, *laveries à gradins*. These methods of freeing the ores from the pulverulent earthy matters, consist in placing them, at their out-put from the mine, upon gratings, and bringing over them a stream of water, which merely takes down through the bars the small fragments, but carries off the pulverulent portions. The latter are received in cisterns, where they are allowed to rest long enough to settle to the bottom. The washing by steps is an extension of the preceding plan. To form an idea, let us imagine a series of gratings placed successively at different levels, so that the water, arriving on the highest, where the ore for washing lies, carries off a portion of it, through this first grate upon a second closer in its bars, thence to a third, &c., and finally into labyrinths or cisterns of deposition.

The *grilles anglaises* are similar to the *sleeping tables* used at Idria. The system of these *en gradins* is represented in fig. 904. There are 5 such systems in the works at Idria, for

the sorting of the small morsels of quicksilver ore, intended for the stamping mill. These fragments are but moderately rich in metal, and are picked up at random, of various sizes, from that of the fist to a grain of dust.

These ores are placed in the chest *a*, below the level of which 7 gratings are distributed, so that the fragments which pass through the first *b*, proceed by an inclined conduit on to the second grate *c*, and so in succession. (See the conduits *l, o, p*.) In front, and on a level with each of the gratings *b, c, d, &c.*, a child is stationed on one of the floors, 1, 2, 3, 4, 5, 6, 7.

A current of water, which falls into the chest *a*, carries the fragments of ore upon the gratings. The pieces which remain upon the two gratings *b* and *c*, are thrown on the adjoining table *v*, where they undergo a sorting by hand; there the pieces are classified, 1. into tongue to be thrown away; 2. into ore for the stamp mill; 3. into ore to be sent directly to the furnace. The pieces which remain on each of the succeeding gratings, *d, e, f, g, h*, are deposited on those of the floors 3 to 7, in front of each. Before every one of these elves a deposite-sieve is established, (see *t, u*), and the workmen in charge of it stand one of the corresponding boxes, marked 8 to 12. The sieve is represented only in front of the chest *h*, for the sake of clearness.

Each of the workmen placed in 8, 9, 10, 11, 12, operates on the heap before him; the upper layer of the deposite formed in his sieve, is sent to the stamping house, and the inferior layer directly to the furnace.

As to the grains which, after traversing the five gratings, have arrived at the chest *x*, they are washed in the two chests *y*, which are analogous to the German chests to be presently described. The upper layer of what is deposited in *y* is sent to the furnace; the rest is treated anew on three tables of percussion, similar to the English brake-sieves, to be presently described.

After several successive manipulations on these tables, an upper stratum of *schlich* is fitted for the furnace; an intermediate stratum, which is washed anew by the same process; and an inferior stratum, that is sent to the system of stamps, fig. 905.

This figure represents the general ground plan of a stamping and washing mill. The stamps *r* are composed of two batteries similar to fig. 903. The ore passes in succession under three pestles of cast iron, each of which is heavier the nearer it is to the sieve through which the sand or pounded matter escapes.

In the upper part of the figure we see issuing from the stamps, two conduits destined to receive the water and the metalliferous sand with which it is loaded. The first, marked *r, s, u*, is used only when a certain quality of ore is stamped, richer in metal than is

usually treated by means of the second conduit, the first being closed. The second conduit, *cr* that employed for ordinary manipulation when the other is shut, is indicated by *r*, 0-7, *n*; then by 0-58 and 0-29. These numbers express the depth of the corresponding portions of this conduit. From *r* to *n*, the conduit or water-course is divided into three portions much shallower, called the *rich conduit*, the *middle conduit*, and the *inferior*. Beyond the basin *n*, the conduit takes the name of labyrinth. There the muddy sediments of ore are deposited: being the finer the further they are from the stamps *r*. Darts indicate the direction of the stream in the labyrinth. On the *German chests*, placed at 3, the sand derived from the rich and middle conduits is treated, in order to obtain three distinct qualities of *schlich*, as already mentioned. *r* is a cloth-covered table, for treating the deposit of the German chests at 3. *m* *n* are two sweep tables (*â balai*), for treating the ore collected in the lower conduit, which precedes the midmost of the three German chests. Upon the three similar tables *n* *r* *v*, are treated in like manner the muddy deposits of the labyrinth, which forms suite to three parallel German chests situated at 3, not shown for want of room in the figure, but connected in three rectangular zigzags with each other, as well as by a transverse branch to the points 0-7 and 0-29. At the upper part of these five sweep tables, the materials which are to undergo washing are agitated in two boxes *o* *o*, by small paddle-wheels.

We shall now describe the *percussion-tables* used in the Hartz, for treating the sand of ore obtained from the conduits represented above.

Figs. 906. 907. and 908, exhibit a plan, a vertical section, and elevation, of one

of these tables, taken in the direction of its length. The arbor or great shaft in position from the stamps is shown in section perpendicular to its axis, at *A*. The cam-wipers are shown round its circumference, one of them having just acted on *n*.

These cams, by the revolution of the arbor, cause alternating movements of horizontal bar of wood *o*, which strikes at the point against a table *d, b, c, u*. The table is suspended by two chains *t*, at its superior end, and two rods at its lower end. After having been pushed the piece *o, u*, it rebounds and strike against a block or brace *n*. A lever *p, q*, serves to adjust the inclination of the moving table, the pivots *q* being points of suspension.

The ore-sand to be washed is placed in the chest *a*, which a current of water moves. The ore floated onwards by water, is carried through a sieve on a sloping small table *x*, under which is concealed the higher end of the moving table *d, b, c, u*; and it then falls on this table, diffusing itself uniformly over its surface. The particles deposited on this table form an oblong *talus* (slope) upon it; the successive percussions that it receives, determine the weightier matters, and consequently those richest in metal, to accumulate towards its upper end at *u*. Now the workman by means of the lever *p*, raises the lower end *d* a little in order to preserve the same

degree of inclination to the surface on which the deposite is strewed. According as the substances are swept along by the water, he is careful to remove them from the middle of the table towards the top, by means of a wooden roller. With this intent, he walks on the table *d b c u*, where the sandy sediment has sufficient consistence to bear him. When the table is abundantly charged with the washed ore, the deposite is divided into three bands or segments *d b*, *b c*, *c u*. Each of these bands is removed separately and thrown into the particular heap assigned to it. Every one of the heaps thus formed becomes afterwards the object of a separate manipulation on a percussion table, but always according to the same procedure. It is sufficient in general to pass twice over this table the matters contained in the heap, proceeding from the superior band *c u*, in order to obtain a pure *schlich*; but the heap proceeding from the intermediate belt *b c*, requires always a greater number of manipulations, and the lower band *d b* still more. These successive manipulations are so associated that eventually each heap furnishes pure *schlich*, which is obtained from the superior band *c u*. As to the lightest particles which the water sweeps away beyond the lower end of the percussion table, they fall into conduits; whence they are lifted to undergo a new manipulation.

Fig. 909 is a profile of a plan which has been advantageously substituted, in the Hartz, for that part of the preceding apparatus which causes the jolt of the piece *o u* against the table *d b c u*. By means of this plan, it is easy to vary, according to the circumstances of a manipulation always delicate, the force of percussion which a bar *x y*, ought to communicate by its extremity *y*. With this view, a slender piece of wood *u* is made to slide in an upright piece, *v x*, adjusted upon an axis at *v*. To the piece *u* a rod of iron is connected, by means of a hinge *z*; this rod is capable of entering more or less into a case or sheath in the middle of the piece *v x*, and of being stopped at the proper point, by a thumb-screw which presses against this piece. If it be wished to increase the force of percussion, we must lower the point *z*; if to diminish it, we must raise it. In the first case, the extremity of the piece *u*, advances so much further under

the cam of the driving shaft *t*; in the second, it goes so much less forwards; whereby the adjustment is produced.

Figs. 910 and 911 represent a complete system of *sleeping tables, tables dormantes*:

911

such as are mounted in Idria. Fig. 911 is the plan, and fig. 910 a vertical section. The mercurial ores, reduced to a sand by stamps like those of fig. 905 pass into a series of conduits *a a*, *b b*, *c c*, which form three successive floors below the level of the floor of the works. The sand taken out of these conduits is thrown into the cells *g*; whence they are transferred into the trough *e*, and water is run upon them by turning two stopcocks for each trough. The sand thus diffused upon each table, runs off with the water by a groove *f*, comes upon a sieve *h*, spreads itself upon the board *g*, and thence falls into the slanting chest, or sleeping table *i k*. The under surface *k* of this chest is pierced with holes, which may be stopped at pleasure with wooden plugs. There is a conduit *m*, at the lower end of each table, to catch the light particles carried off by the water out of the chest *i k*, through the holes properly opened, while the denser parts are deposited upon the bottom of this chest. A general conduit *n* passes across at the foot of all the chests *i k*; it receives the refuse of the washing operations.

Fig. 912 is a set of stamping and washing works for the ores of argentiferous galena, as mounted at Bockwiese, in the district of Zellerfeldt, in the Hartz.

a is the stamp mill and its subsidiary parts; among which are *a*, the driving or

main shaft; *b*, the overshot water-wheel; *c c*, six strong rings or hoops of cast iron, for receiving each a cam or tappet; *g*, the brake of the machine; *k, k, k*, the three standards of the stamps; *l l*, &c. six pestles of pine wood, shod with lumps of cast iron. There are two chests, out of which the ore to be ground falls spontaneously into the two troughs of the stamps. Of late years, however, the ore is mostly supplied by hand; the water-course terminates a short distance above the middle of the wheel *b*. There is a stream of water for the service of the stamps, and conduits proceeding from it, to lead the water into the two stamp troughs; the conduit of discharge is common to the two batteries or sets of stamps through which the water carries off the sand or stamped ore. There is a moveable table of separation, mounted with two sieves. The sands pass immediately into the conduit placed upon a level with the floor, and separated into two compartments, the first of which empties its water into the second. There are two boards of separation, or tables, laid upon the ground, with a very slight slope of only 15 inches from their top to their bottom. Each of these boards is divided into four cases with edges; the whole being arranged so that it is possible, by means of a flood-gate or sluice, to cause the superfluous water of the case to pass into the following ones. Thus the work can go on without interruption, and alternately upon the two boards. There are winding canals in the labyrinth, *n, n, n*, in which are deposited the particles carried along by the water which has passed upon the boards. The depth of these canals gradually increases from 12 to 20 inches, to give a suitable descent for maintaining the water-flow. At *d*, two percussion tables are placed. *f g* are two German chests. *h j* are two percussion tables, which are driven by the cams *z z*, fixed upon the main shaft *x y*. *k k'* are two sloping sweep tables (*à balai*).

box, without any edge at the side next the chest, is placed, containing the ore to be washed. The water is allowed to fall upon the bolster in a thin sheet.

The *sleeping tables* have upright edges; they are from 4 to 5 yards long, nearly 2 yards wide, and have fully a yard of inclination.

The preceding tables are sometimes covered with cloth, particularly in treating ores that contain gold, on a supposition that the woollen or linen fibres would retain more surely the metallic particles; but this method appears on trial to merit no confidence, for it produces a very impure *schlich*.

Fig. 913 is a swing-sieve employed in the Hartz, for sifting the small fragments of the ore of argentiferous lead.

Such an apparatus is usually set up in the outside of a stamp and washing mill; its place being denoted by the letter *A*, in fig. 905. The two moveable chests or boxes *A B*, of the sieve, are connected together, at their lower ends, with an upright rod, which terminates at one of the arms of a small balance beam, mounted between the driving shaft of the stamps and the sieve, perpendicularly to the length of both. The opposite arm of this beam carries another upright rod, which ears (cams or *mentonnets*), placed on purpose upon the driving shaft, may push down. During this movement the two lower ends *A, B*, are raised; and when the peg-cam of the shaft quits the rod which it had depressed, the swing chests fall by their own weight. Thus they

are made to vibrate alternately upon their axes. The small ore is put into the upper part of the chest *A*, over which a stream of water falls from an adjoining conduit. The fragments which cannot pass through a cast iron grid in the bottom of that chest, are sorted by hand upon a table in front of *A*, and they are classed by the workman, either among the ores to be stamped, whether dry or wet, or among the rubbish to be thrown away, or among the copper ores to be smelted by themselves. As to the small particles which fall through the grid upon the chest *B*, supplied also with a stream of water, they descend successively upon two other brass wire sieves, and also through the iron wire *r*, in the bottom of *B*.

In certain mines of the Hartz, tables called *à balais*, or *sweeping tables*, are employed. The whole of the process consists in letting flow, over the sloping table, in successive currents, water charged with the ore, which is deposited at a less or greater distance, as also pure water for the purpose of washing the deposited ore, afterwards carried off by means of this sweeping operation.

At the upper end of these *sweep-tables*, the matters for washing are agitated in a chest, by a small wheel with vanes, or flap-boards. The conduit of the muddy waters opens above a little table or shelf; the conduit of pure water, which adjoins the preceding, opens below it. At the lower part of each of these tables, there is a transverse slit, covered by a small door with hinges, opening outwardly, by falling back towards the foot of the table. The water spreading over the table, may at pleasure be let into this slit, by raising a bit of leather which is nailed to the table, so as to cover the small door when it is in the shut position; but when this is opened, the piece of leather then hangs down into it. Otherwise the water may be allowed to pass freely above the leather, when the door is shut. The same thing may be done with a similar opening placed above the conduit. By means of these two slits, two distinct qualities of *schlich* may be obtained, which are deposited into two distinct conduits or canals. The refuse of the operation is turned into another conduit, and afterwards into ulterior reservoirs, whence it is lifted out to undergo a new washing.

In the percussion tables, the water for washing the ores is sometimes spread in slender streamlets, sometimes in a full body, so as to let two cubic feet escape per minute. The number of shocks communicated per minute, varies from 15 to 36; and the table may be pushed out of its settled position at one time, three quarters of an inch, at another nearly 8 inches. The coarse ore-sand requires in general less water, and less slope of table, than the fine and pasty sand.

The *mechanical* operations which ores undergo, take place commonly at their out-put from the mine, and without any intermediate operation. Sometimes, however, the hardness of certain *gangues* (vein-stones), and of certain iron ores, is diminished by subjecting them to calcination previously to the breaking and stamping processes.

When it is intended to wash certain ores, an operation founded on the difference of their specific gravities, it may happen that by slightly changing the chemical state of the substances that compose the ore, the earthy parts may become more easily separable, as also the other foreign matters. With this view, the ores of tin are subjected to a roasting, which by separating the arsenic, and oxydizing the copper which are intermixed, furnishes the means of obtaining, by the subsequent washing, an oxyde of tin much purer than could be otherwise procured. In general, however, these are rare cases; so that the washing almost always immediately succeeds the picking and stamping; and the roasting comes next, when it needs to be employed.

The operation of roasting is in general executed by various processes, relatively to the nature of the ores, the quality of the fuel, and to the object in view. The greatest economy ought to be studied in the fuel, as well as the labor; two most important circumstances, on account of the great masses operated upon.

Three principal methods may be distinguished; 1. the roasting in a heap in the open air, the most simple of the whole; 2. the roasting executed between little walls, and which may be called *case-roasting* (*rost-stadeln*, in German); and 3. roasting in furnaces.

We may remark, as to the description about to be given of these different processes, that in the first two, the fuel is always in immediate contact with the ore to be roasted, whilst in furnaces, this contact may or may not take place.

1. The roasting in the open air, and in heaps more or less considerable, is practised upon iron ores, and such as are pyritous or bituminous. The operation consists in general in spreading over a plane area, often bottomed with beaten clay, billets of wood arranged like the bars of a grilliron, and sometimes laid crosswise over one another, so as to form a uniform flat bed. Sometimes wood charcoal is scattered in, so as to fill up the interstices, and to prevent the ore from falling between the other pieces of the fuel. Coal is also employed in moderately small lumps; and even occasionally turf. The ore, either simply broken into pieces, or even sometimes under the form of *schlich*, is piled up over the fuel; most usually alternate beds of fuel and ore are formed.

The fire, kindled in general at the lower part, but sometimes, however, at the middle chimney, spreads from spot to spot, putting the operation in train. The combustion must be so conducted as to be slow and suffocated, to prolong the ustulation, and let the whole mass be equally penetrated with heat. The means employed to direct the fire, are to cover outwardly with earth the portions where too much activity is displayed, and to pierce with holes or to give air to those where it is imperfectly developed. Rains, winds, variable seasons, and especially good primary arrangements of a calcination, have much influence on this process, which requires, besides, an almost incessant inspection at the beginning.

Nothing in general can be said as to the consumption of fuel, because it varies with its quality, as well as with the ores and the purpose in view. But it may be laid down as a good rule, to employ no more fuel than is strictly necessary for the kind of calcination in hand, and for supporting the combustion; for an excess of fuel would produce, besides an expense uselessly incurred, the inconvenience, at times very serious, of such a heat as may melt or vitrify the ores; a result entirely the reverse of a well-conducted ustulation.

Figs. 914, 915, 916, represent the roasting in mounds, as practised near Goslar in the

Hartz, and at Chessy in the department of the Rhone. Fig. 914 is a vertical section in the line *h c* of figs. 915 and 916. In fig. 915 there is shown in plan, only a little more than one half of the quadrangular truncated pyramid, which constitutes the heap. Fig. 916 shows a little more than one fourth of a bed of wood, arranged at the bottom of the pyramid, as shown by *a a*, fig. 914 and *c g h*, fig. 916. *c* is a wooden chimney,

formed within the heap of ore, at whose bottom *c* there is a little parcel of charcoal; *d d* are large lumps of ore distributed upon the wooden pile *a a*; *e e* are smaller fragments, to cover the larger; *f f* is rubbish and clay laid smoothly in a slope over the whole. *g*, fig. 916 a passage for air left under the bed of billets; of which there is a similar one in each of the four sides of the base *a a*, so that two principal currents of air cross under the upright axis *c c*, of the truncated pyramid indicated in fig. 914.

The kindling is thrown in by the chimney *c*. The charcoal *c*, and the wood *a a*, take fire; the sulphureous ores *d e f* are heated to such a high temperature as to vaporize the sulphur. In the

Lower Hartz, a heap of this kind continues roasting during four months.

2. The second method. The difficulty of managing the fire in the roasting of substances containing little sulphur, with the greater difficulty of arranging and supporting in their place the *schlichs* to be roasted, and last of all, the necessity of giving successive fires to the same ores, or to inconsiderable quantities at a time, have led to the contrivance of surrounding the area on which the roasting takes place with three little walls, or with four, leaving a door in the one in front. This is what is called a *walled area*, and sometimes, improperly enough, a roasting furnace. Inside of these little walls, about 3 feet high, there are often vertical conduits or chimneys made to correspond with an opening on the ground level, in order to excite a draught of air in the adjacent parts. When the roasting is once set agoing, these chimneys can be opened or shut at their upper ends, according to the necessities of the process.

Several such furnaces are usually erected in connexion with each other by their lateral walls, and all terminated by a common wall, which forms their posterior part; sometimes they are covered with a shed supported partly by the back wall, built sufficiently high for this purpose. These dispositions are suitable for the roasting of *schlichs*, and in general of all matters which are to have several fires; a circumstance often indispensable to a due separation of the sulphur, arsenic, &c.

3 The furnaces employed for roasting the ores and the *matte*s differ much, according

to the nature of the ores, and the size of the lumps. We shall content ourselves with referring to the principal forms.

When iron ores are to be roasted, which require but a simple calcination to disengage the combined water and carbonic acid, egg-shaped furnaces, similar to those in which limestone is burned in contact with fuel, may be conveniently employed; and they present the advantage of an operation which is continuous with a never-cooling apparatus. The analogy in the effects to be produced is so perfect, that the same furnace may be used for either object. Greater dimensions may, however, be given to those destined for the calcination of iron ores. But it must be remembered that this process is applicable only to ores broken into lumps, and not to ores in grains or powder.

It has been attempted to employ the same method a little modified, for the roasting of ores of sulphuret of copper and pyrites, with the view of extracting a part of the sulphur. More or less success has ensued, but without ever surmounting all the obstacles arising from the great fusibility of the sulphuret of iron. For sometimes it runs into one mass, or at least into lumps agglutinated together in certain parts of the furnace, and the operation is either stopped altogether, or becomes more or less languid; the air not being able to penetrate into all the parts, the roasting becomes consequently imperfect. This inconvenience is even more serious than might at first sight appear; for, as the ill-roasted ores now contain too little sulphur to support their combustion, and as they sometimes fall into small fragments in the cooling, they cannot be passed again through the same furnace, and it becomes necessary to finish the roasting in a reverberatory hearth, which is much more expensive.

In the Pyrenees, the roasting of iron ores is executed in a circular furnace, so disposed that the fuel is contained and burned in a kind of interior oven, above which lie the pieces of ore to be calcined. Sometimes the vault of this oven, which sustains the ore, is formed of bricks, leaving between them openings for the passage of the flame and the smoke, and the apparatus then resembles certain pottery kilns; at other times the vault is formed of large lumps of ore, carefully arranged as to the intervals requisite to be left for draught over the arch. The broken ore is then distributed above this arch, care being taken to place the larger pieces undermost. This process is simple in the construction of the furnace, and economical, as branches of trees, without value in the forest, may be employed in the roasting. See *Lime-kiln* figures.

In some other countries, the ores are roasted in furnaces very like those in which porcelain is baked; that is to say, the fuel is placed exteriorly to the body of the furnace in a kind of brick shafts, and the flame traverses the broken ore with which the furnace is filled. In such an apparatus the calcination is continuous.

When it is proposed to extract the sulphur from the iron pyrites, or from pyritous minerals, different furnaces may be employed, among which that used in Hungary deserves notice. It is a rectangular parallelepiped of four walls, each of them being perforated with holes and vertical conduits which lead into chambers of condensation, where the sulphur is collected. The ore placed between the four walls on billets of wood arranged as in *figs.* 914, 915, 916, for the great roastings in the open air, is calcined with the disengagement of much sulphur, which finds more facility in escaping by the lateral conduits in the walls, than up through the whole mass, or across the upper surface covered over with earth; whence it passes into the chambers of condensation. In this way upwards of a thousand tons of pyrites may be roasted at once, and a large quantity of sulphur obtained.—See *COPPER*.

Roasting of Pyrites.—*Figs.* 917, 918, represent a furnace which has been long employed at Fahlun in Sweden, and

several other parts of that kingdom, for roasting iron pyrites in order to obtain sulphur. This apparatus was constructed by the celebrated Gahn. *Fig.* 917 is a vertical section, in the line *k d n o* of *fig.* 918 which is a plan of the furnace; the top being supposed to be taken off. In both figures the conduit may be imagined to be broken off at *e*; its entire length in a straight line is 43 feet

beyond the dotted line, *e n*, before the bend, which is an extension of this conduit. Upon the slope *a b* of a hillock *a b c*, lumps *r* of iron pyrites are piled upon the pieces of wood *i i* for roasting. A conduit *d f e* forms the continuation of the space denoted by *r*, which is covered by stone slabs so far as *f*; and from this point to the chamber *h* it is constructed in boards. At the beginning of this conduit, there is a recipient *g*. The chamber *h* is divided into five chambers by horizontal partitions, which permit the circulation of the

vapors from one compartment to another. The ores r being distributed upon the billets of wood i , whenever these are fairly kindled, they are covered with small ore, and then with rammed earth l . Towards the point m , for a space of a foot square, the ores are covered with moveable stone slabs, by means of which the fire may be regulated, by the displacement of one or more, as may be deemed necessary. The liquid sulphur runs into the recipient g , whence it is laded out from time to time. The sublimed sulphur passes into the conduit f and the chamber h , from which it is taken out, and washed with water, to free it from sulphuric acid, with which it is somewhat impregnated; it is afterwards distilled in cast-iron retorts. The residuum of the pyrites is turned to account in Sweden, for the preparation of a common red color much used as a pigment for wooden buildings.

The reverberatory furnace affords one of the best means of ustulation, where it is requisite to employ the simultaneous action of heat and atmospheric air to destroy certain combinations, and to decompose the sulphurets, arseniurets, &c. It is likewise evident that the facility thus offered of stirring the matters spread out on the sole, in order to renew the surfaces, of observing their appearances, of augmenting or diminishing the degree of heat, &c., promise a success much surer, a roasting far better executed, than by any other process. It is known, besides, that flame mingled with much undecomposed air issuing from the furnace, is highly oxydizing, and is very fit for burning away the sulphur, and oxydizing the metals. Finally, this is almost the only method of rightly roasting ores which are in a very fine powder. If it be not employed constantly and for every kind of ore, it is just because more economy is found in practising calcination in heaps, or on areas enclosed by walls; besides, in certain mines, a very great number of these furnaces, and many workmen, would be required to roast the considerable body of ores that must be daily smelted. Hence there would result from the construction of such apparatus and its maintenance a very notable outlay, which is saved in the other processes.

But in every case where it is desired to have a very perfect roasting, as for blende from which zinc is to be extracted, for sulphuret of antimony, &c., or even for ores reduced to a very fine powder, and destined for amalgamation, it is proper to perform the operation in a reverberatory furnace. When very fusible sulphurous ores are treated, the workman charged with the calcination must employ much care and experience, chiefly in the management of the fire. It will sometimes, indeed, happen, that the ore partially fuses; when it becomes necessary to withdraw the materials from the furnace, to let them cool and grind them anew, in order to recommence the operation. The construction of these furnaces demands no other attention than to give to the sole or laboratory the suitable size, and so to proportion to this the grate and the chimney that the heating may be effected with the greatest economy.

The reverberatory furnace is always employed to roast the ores of precious metals, and especially those for amalgamation; as the latter often contain arsenic, antimony, and other volatile substances, they must be disposed of in a peculiar manner.

The sole, usually very spacious, is divided into two parts, of which the one farthest off from the furnace is a little higher than the other. Above the vault there is a space or chamber in which the ore is deposited, and which communicates with the laboratory by a vertical passage; which serves to allow the ore to be pushed down, when it is dried and a little heated. The flame and the smoke which escape from the sole or laboratory pass into condensing chambers, before entering into the chimney of draught, so as to deposit in them the oxyde of arsenic and other substances. When the ore on the part of the sole farthest from the grate has suffered so much heat as to begin to be roasted, has become less fusible, and when the roasting of that in the nearer part of the sole is completed, the former is raked towards the fire-bridge, and its ustulation is finished by stirring it over frequently with a paddle, skilfully worked, through one of the doors left in the side for this purpose. The operation is considered to be finished when the vapors and the smell have almost wholly ceased; its duration depending obviously on the nature of the ores.

When this furnace is employed to roast very arsenical ores, as the tin ores of Schlackenwald in Bohemia, and at Ehrenfriedensdorf in Saxony, the arsenical pyrites of Geyer (in Saxony), &c., the chambers of condensation for the arsenious acid are much more extensive than in the furnaces commonly used for roasting galena, copper, or even silver ores.

Figs. 919, 920, 921, represent a reverberatory furnace employed in the smelting works of Lautenthal, in the Hartz, for roasting the schlichs of lead ores, which contain much blende or sulphuret of zinc. In fig. 919 we see that the two parts A , B , C , are absolutely like, the two furnaces being built in one body of brickwork. Fig. 920 is the plan of the furnace B , C , taken at the level EF of fig. 919. Fig. 921 is a vertical section of the similar furnace A , B , taken in the prolongation of the line GH in fig. 920.

a is the fire-place of the furnace, its grate and ash-pit. *b* is the conduit of vaporization, which communicates with the chambers *c*; *c*, chambers into which the vaporized

substances are deposited; *d*, chimney for the escape of the smoke of the fire place *a*, after it has gone through the space *b c c*; *e*, is the charging door, with a hook hanging

in front to rest the long iron rake upon, with which the materials are turned over; *f*, chamber containing a quantity of schlich destined for roasting; this chamber communicates with the vaulted corridor (gallery) *d*, seen in fig. 919; *g*, orifice through which the schlich is thrown into the furnace; *h*, area or hearth of the reverberatory furnace, of which the roof is certainly much too high; *i*, channels for the escape of the watery vapors; *k*, *l*, front arcade, between which and the furnace, properly speaking, are the two orifices of the conduits, which terminate at the channels *m*, *m'*. *m* is the channel for carrying towards the chimney *d*, the vapors which escape by the door *e'*. *n* is a walled-up door, which is opened from time to time, to take out of the chambers *c*, *c*, the substances that may be deposited in them.

At the smelting works of Lautenthal, in such a roasting furnace, from 6 to 9 quintals (cwts.) of schlich are treated at a time, and it is stirred frequently with an iron rake upon the altar *h*. The period of this operation is from 6 to 12 hours, according as the schlich may be more or less dry, more or less rich in lead, or more or less charged with blende.

When the latter substance is abundant, the process requires 12 hours, with about 60 cubic feet of cleft billets for fuel.

In such furnaces are roasted the cobalt ores of Schneeberg in Saxony, the tin ores of Schlackenwald in Bohemia, of Ehrenfriedersdorf in Saxony, and elsewhere; as also the arsenical pyrites at Geyer in Saxony. But there are poison towers and extensive condensing chambers attached in the latter case. See ARSENIC.

Figs. 922, 923, 924, represent the reverberatory furnace generally employed in the

Hartz, in the district of Mansfeldt, Saxony, Hungary, &c., for the treatment of black copper, and for refining rose copper upon the great scale. An analogous furnace is used at Andreasberg for the liquefaction or purification of the mattes, and for workable lead when it is much loaded with arsenic.

Fig. 922 presents the elevation of the furnace parallel to the line *i k*, of the plan fig. 923; which plan is taken at the level of the tuyère *n*,

of fig. 924; fig. 924 is a vertical section in the line *l m*, fig. 923. *k* represents one of two basins of reception, brasqued with clay and charcoal; *n*, *n*, two tuyères, through which enters the blast of two pairs of bellows, like those shown at Cupellation of SILVER; *q*, door by which the matter to be melted is laid upon the sole of the furnace; *v*, *v*, two points where the sole is perforated, when necessary to run off the melted matter into either of the basins *h*; *x*, door through which the slags or cinders floating upon the sur-

face of the melted metal are raked out; *y*, door of the fire-place. The fuel is laid upon a grate above an ash-pit, and below the arch of a reverberatory which is contiguous to the dome or cap of the furnace properly so called. In the section, *fig. 924* the following parts may be noted; 1, 2, 3, mason-work of the foundation; 4, vapor channels or con-

duits, for the escape of the humidity; 5, bed of clay; 6, brasque composed of clay and charcoal, which forms the concavity of the hearth.

Figs. 925, 926, 927, show the furnace employed for liquation in one of the principal smelting works of the Hartz. *Fig. 927* exhibits the working area charged with the liquation cakes and charcoal, supported by sheets of wrought iron; being an image of the process in action. *Fig. 926* is the plan, in the line *r c*, of *fig. 925*.

A liquation cake is composed of—

Black copper holding at least 5 or 6 *loths* ($2\frac{1}{2}$ or 3 oz.) of silver per cwt., and weighing 90 to 96 lbs.

Lead obtained from litharge, 2 cwt. Litharge, $\frac{1}{2}$ cwt.

From 30 to 32 cakes are successively worked in one operation, which lasts about 5 hours; the furnace is brought into action, as usual, with the aid of slags; then a little litharge is added; when the lead begins to flow, the copper is introduced, and when the copper flows, lead is added, so that the mixture of the metals may be effected in the best way possible.

From 8 to 16 of these cakes (*pains*) are usually placed in the liquation furnace, *figs. 925, 926, 927*. The operation lasts 3 or 4 hours, in which time about $1\frac{1}{2}$ quintals of charcoal are consumed. The cakes are covered with burning charcoal, supported, as I have said, by the iron plates. The workable lead obtained flows off towards the basin in front of the furnace; whence it is ladled out into moulds set alongside. See *fig. 926* If the lead thus obtained be not sufficiently rich in silver to be worth cupellation, it is employed to form new liquation cakes. When it contains from 5 to 6 *loths* of silver per cwt., it is submitted to cupellation in the said smelting works. See SILVER.

The *trompe*, or water blowing engine, *figs. 928, 929, 930*. *Fig. 928* is the elevation; *fig. 929* is a vertical section, made at right angles to the elevation. The machine is formed of two cylindrical pipes, the bodies of the *trompe* *b b*, set upright, called the funnels, which terminate above in a water cistern *a*, and below in a close basin under *c*, called the *tub* or

drum. The conical part *p*, of the funnel has been called *étranguillon*, being *strangled*, as it were, in order that the water discharged into the body of the trompe shall not fill the

pipe in falling, but be divided into many streamlets. Below this narrow part, eight holes, *g g*, are perforated obliquely through the substance of the trompe, called the vent-holes or nostrils, for admitting the air, which the water carries with it in its descent. The air afterwards parts from the water, by dashing upon a cast-iron slab, placed in the drum upon the pedestal *d*. An aperture *l*, at the bottom of the drum, allows the water to flow away after its fall; but, to prevent the air from escaping along with it, the water as it issues is received in a chest *l m n o*, divided into two parts by a vertical slide-plate between *m n*. By raising or lowering this plate, the water may be maintained at any desired level within the drum, so as to give the included air any determinate degree of pressure. The superfluous water then flows off by the hole *o*.

The air-pipe *e*, fig. 929 is fitted to the upper part of the drum; it is divided, at the point *f*, into three tubes, of which the principal one is destined for the furnace of cupellation, while the other two *g g*, serve for different melting furnaces. Each of these tubes ends in a leather pocket, and an iron nose-pipe *k*, adjusted in the tuyère of the furnace. At Pesey, and in the whole of Savoy, a floodgate is fitted into the upper cistern *a*, to regulate the admission of water into the trompe; but in Carniola, the funnel *p* is closed with a wooden plug, suspended to a cord, which goes round a pulley mounted upon a horizontal axis, as shown in fig. 930. By the plug *a* being raised more or less, merely the quantity of water required for the operation is admitted. The plug is pierced lengthwise with an oblique hole *c c*, in which the small tube *c* is inserted, with its top some way above the water level, through which air may be admitted into the heart of the column descending into the trompe *p g*.

The ordinary height of the trompe apparatus is about 26 or 27 feet to the upper level of the water cistern; its total length is 11 mètres (36 feet 6 inches), and its width 2 feet,

to give room for the drums. It is situated 10 metres (33½ feet) from the melting furnace. This is the case at the smelting works of Jauerberg, in Upper Carniola.

OF THE ASSAY OF ORES.

Assays ought to occupy an important place in metallurgic instructions, and there is reason to believe that the knowledge of assaying is not sufficiently diffused, since its practice is so often neglected in smelting houses. Not only ought the assays of the ores under treatment to be frequently repeated, because their nature is subject to vary; but the different products of the furnaces should be subjected to reiterated assays, at the several periods of the operations. When silver or gold ores are in question, the docimastic operations, then indispensable, exercise a salutary control over the metallurgic processes, and afford a clear indication of the quantities of precious metal which they ought to produce.

By the title *Assays*, in a metallurgic point of view, is meant the method of ascertaining for any substance whatever, not only the presence and the nature of a metal, but its proportional quantity. Hence the operations which do not lead to a precise determination of the metal in question, are not to be arranged among the assays now under consideration. Experiments made with the blow-pipe, although capable of yielding most useful indications, are like the touchstone in regard to gold, and do not constitute genuine assays.

Three kinds of assays may be practised in different circumstances, and with more or less advantage upon different ores. 1. The mechanical assay; 2. the assay by the dry way; 3. the assay by the humid way.

1. *Of mechanical assays.*—These kinds of assays consist in the separation of the substances mechanically mixed in the ores, and are performed by a hand-washing, in a small trough of an oblong shape, called a *sevilla*. After pulverizing with more or less pains the matters to be assayed by this process, a determinate weight of them is put into this wooden bowl with a little water; and by means of certain movements and some precautions, to be learned only by practice, the lightest substances may be pretty exactly separated, namely, the earthy gangues from the denser matter or metallic particles, without losing any sensible portion of them. Thus a *schlich* of greater or less purity will be obtained, which may afford the means of judging by its quality of the richness of the assayed ores, and which may thereafter be subjected to assays of another kind, whereby the whole metal may be insulated.

Washing, as an assay, is practised on auriferous sands; on all ores from the *stamps*, and even on *schlichs* already washed upon the great scale, to appreciate more nicely the degree of purity they have acquired. The ores of tin in which the oxyde is often disseminated in much earthy gangue, are well adapted to this species of assay, because the tin oxyde is very dense. The mechanical assay may also be employed in reference to the ores whose metallic portion presents a uniform composition, provided it also possesses considerable specific gravity. Thus the ores of sulphuret of lead (galena) being susceptible of becoming almost pure sulphurets (within 1 or 2 per cent.) by mere washing skilfully conducted, the richness of that ore in pure galena, and consequently in lead, may be at once concluded; since 120 of galena contain 104 of lead, and 16 of sulphur. The sulphuret of antimony mingled with its gangue may be subjected to the same mode of assay, and the result will be still more direct, since the crude antimony is brought into the market after being freed from its gangue by a simple fusion.

The assay by washing is also had recourse to for ascertaining if the *scoriae* or other products of the furnaces contain some metallic grains which might be extracted from them by stamping and washing on the great scale; a process employed considerably with the *scoriae* of tin and copper works.

Of assays by the dry way.—The assay by the dry way has for its object, to show the nature and proportion of the metals contained in a mineral substance. To make a good assay, however, it is indispensably necessary to know what is the metal associated with it, and even within certain limits, the quantity of the foreign bodies. Only one metal is commonly looked after; unless in the case of certain argentiferous ores. The mineralogical examination of the substances under treatment, is most commonly sufficient to afford data in these respects; but the assays may always be varied with different views, before stopping at a definite result; and in every instance, only such assays can be confided in, as have been verified by a double operation.

This mode of assaying requires only a little experience, with a simple apparatus; and is of such a nature as to be practised currently in the smelting works. The air furnace and crucibles employed are described in all good elementary chemical books. These assays are usually performed with the addition of a flux to the ore, or some agent for separating the earthy from the metallic substances; and they possess a peculiar advantage relative to the smelting operations, because they offer many analogies between

results on the great scale and experiments on the small. This may even enable us often to deduce, from the manner in which the assay has succeeded with a certain flux, and at a certain degree of heat, valuable indications as to the treatment of the ore in the great way. See FURNACE.

In the smelting houses which purchase the ore, as in Germany, it is necessary to bestow much attention upon the assays, because they serve to regulate the quality and the price of the *schlichs* to be delivered. These assays are not by any means free from difficulties, especially when ores containing several useful metals are treated, and which are to be dosed or proportioned; ores, for example, including a notable quantity of lead, copper, and silver, mixed together.

In the central works of the Hartz, as well as in those of Saxony, the *schlichs* as delivered are subjected to docimastic assays, which are verified three times, and by three different persons, one of whom is engaged for the interests of the mining partners, another for that of the smelting house, and a third as arbiter in case of a difference. If the first two results of assaying differ by $\frac{1}{2}$ *loth* (or $\frac{1}{2}$ ounce) of silver per cwt. of *schlich*, the operations must be resumed; but this rarely happens. When out of the three assays, the one differs from the two others by no more than $\frac{1}{4}$ *loth* of silver per cwt., but by more in one, and by less in another, the mean result is adopted. As to the contents of the *schlich* in lead, the mean results of the assays must be taken. The differences allowed are three pounds for the *schlich*, when it contains from 12 to 30 per cent. of lead, increasing to six pounds for *schlich*, when it contains less than 55 per cent. of that metal.

Assaying forms, in great establishments, an important object in reference to time and expense. Thus, in the single work of Franckenscharn, in the Hartz, no less than 300 assays have to be made in a threefold way, every Monday, without taking into account the several assays of the smelting products which take place every Thursday. Formerly fluxes more or less compound were employed for these purposes, and every assay cost about fifteen pence. At present all these assays are made more simply, by much cheaper methods, and cost a penny farthing each upon an average.

Of the assays by the humid way.—The assays by the humid way, not reducible to very simple processes, are true chemical analyses, which may in fact be applied with much advantage, either to ores, or to the products of the furnace; but which cannot be expected to be practised in smelting-houses, on account of the complication of apparatus and reagents they require. Moreover, an expert chemist is necessary to obtain results that can be depended on. The directors of smelting-houses, however, should never neglect any opportunities that may occur of submitting the materials operated upon, as well as their products, to a more thorough examination than the dry way alone can effect. One of the great advantages of similar researches is to discover and appreciate the minute quantities of injurious substances which impair the malleability of the metals, which give them several bad qualities, about whose nature and cause more or less error and uncertainty prevail. Chemical analysis, rightly applied to metallurgy, cannot fail to introduce remarkable improvements into the processes. See the different metals, in their alphabetical places.

For assays in the dry way, both of stony and metallic minerals, the process of Dr. Abich deserves recommendation. It consists in mixing the pulverized mineral with 4 or 6 times its weight of carbonate of baryta in powder, fusing the mixture at a white heat, and then dissolving it, after it cools, in dilute muriatic acid. The most refractory minerals, even corundum, cyanate, staurolite, zircon, and feldspar, yield readily to this treatment. This process may be employed with advantage upon poor refractory ores. The platinum crucible, into which the mixed materials are put for fusion, should be placed in a Hessian crucible, and surrounded with good coke.

The manganese raised in England exceeds 2000 tons.

M. Heron de Villefosse inserted in the last number of the *Annales des Mines* for 1827, the following statistical view of the metallic products of France:—

	Tons.
Lead in pigs (<i>saumons</i>)	103
Litharge	513
Sulphuret of lead, ground galena (<i>alquifoux</i>)	112
Black copper	164
Antimony	91
Manganese	765
Crude cast-iron	25,606
Bar iron	127,643
Steel	3,500
Silver in ingots	1 $\frac{1}{2}$

The total value of which is estimated at 30 millions of francs, or about 3,400,000 pounds sterling.

METALS. (*Métal*, Fr.; *Metalle*, Germ.) are by far the most numerous class of undecomposed bodies in chemical arrangements. They amount to 43; of which 7 form, with oxygen, bodies possessed of alkaline properties: these are, 1. potassium; 2. sodium; 3. lithium; 4. barium; 5. strontium; 6. calcium; 7. magnesium; for even magnesium, the last and feeblest base, tinges turmeric brown, and red cabbage, green. The next five metals form, with oxygen, the earths proper; they are, 8. yttrium; 9. glaucium; 10. aluminum; 11. zirconium; 12. thorium. The remaining 31 may be enumerated in alphabetical order, as they hardly admit of being grouped into subdivisions with any advantage. They are as follows: 13. antimony; 14. arsenic; 15. bismuth; 16. cadmium; 17. cerium; 18. chromium; 19. cobalt; 20. copper; 21. gold; 22. iridium; 23. iron; 24. lead; 25. manganese; 26. mercury; 27. molybdenum; 28. nickel; 29. osmium; 30. palladium; 31. platinum; 32. rhodium; 33. silver; 34. tantalum; 35. tellurium; 36. tin; 37. titanium; 38. tungsten; 39. vanadium; 40. uranium; 41. zinc; 42. niobium; 43. pelopium.

1. They are all, more or less, remarkable for a peculiar lustre, called the metallic. This property of strongly reflecting light is connected with a certain state of aggregation of their particles, but is possessed, superficially at least, by mica, animal charcoal, selenium, polished indigo,—bodies not at all metallic.

2. The metals are excellent conductors of caloric, and most of them also of electricity, though probably not all. According to Despretz, they possess the power of conducting heat according to the following numbers:—gold, 1000; platinum, 981; silver, 973; copper, 898; iron, 374; zinc, 363; tin, 304; lead, 179.6.

Bequerel gives the following table of metals, as to electrical conduction:—

Copper, 100; gold, 93.6; silver, 73.6; zinc, 28.5; platina, 16.4; iron, 15.8; tin, 15.4; lead, 8.2; mercury, 3.5; potassium, 1.23.

The metals which hardly, if at all, conduct electricity, are, zirconium; aluminum; tantalum, in powder; and tellurium.

3. Metals are probably opaque; yet gold leaf, as observed by Newton, seems to transmit the green rays, for objects placed behind it in the sunbeam appear green. This phenomena has, however, been ascribed to the rays of light passing through an infinite number of minute fissures in the thinly hammered gold.

4. All metals are capable of combining with oxygen, but with affinities and in quantities extremely different. Potassium and sodium have the strongest affinity for it, arsenic and chromium the feeblest. Many metals become acids by a sufficient dose of oxygen, while, with a smaller dose, they constitute salifiable bases.

5. Metals combine with each other, forming a class of bodies called alloys, except when one of them is mercury, in which case the compound is styled an amalgam.

6. They combine with hydrogen, into *hydurets*; with carbon, into *carburets*; with sulphur, into *sulphurets*; with phosphorus, into *phosphurets*; with selenium, into *selenurets*; with boron, into *borurets* (*borides*?); with chlorine, into *chlorides*; with iodine, into *iodides*; with cyanogen, into *cyanides*; with silicon, into *silicides*; and with fluorine, into *fluorides*.

7. Metallic salts are definite compounds, mostly crystalline, of the metallic oxides with the acids. See HALOGEN.

METEORITES, (*Aerolithes*, Fr.), are stones of a peculiar aspect and composition, which have fallen from the air.

METER, GAS. Since the article Gas was printed I have had occasion to examine very carefully the construction, performance, and comparative merits of the four gas-meters most generally used in Great Britain, and have been led to conclude that the surmises concerning the correctness of the indications of several of them, but too well founded. The instruments on which my observations were made were all new, and just out of the hands of their respective patentees.

1. The meter of Mr. West is, no doubt, accurate while the water-line is rightly adjusted; but as I find that it will admit an extra pint of water, it may be rendered unjust towards the consumers of gas; and then if it receives a little more water by condensation of vapor, or by accident, its siphon gets filled, which causes the extinction of the lights.

2. The meter of Mr. Bottom has also several defects, and occasions nuisance by letting its overflow water trickle upon the floor.

3. The meter of Mr. Crossley may be made to err in its measurements fully 20 per cent. by dexterous repletion with water, and that in favor of the gas companies.

These three meters are furnished with the vertical float valve, so apt to rust and stick; they also allow gas to escape at the discharge plug, to the imminent risk of occasioning fire with ignorant or careless servants; and finally, they have the complex dial-plate indexes, so liable to misapprehension.

4. The meter of Mr. Edge. This instrument is quite exempt from all the above defects, and is equally delicate and just in its indications, being mounted with a lever valve of great mobility, and a new index, which any one who knows numbers cannot miscount. I have subjected this meter to every kind of test, and find that it cannot be made to give false indications, either by awkwardness or intention. Its inventor is therefore well entitled to the warm patronage both of the public and all gas companies who love fair dealing.

METHYLENE, a peculiar liquid compound of carbon and hydrogen, extracted from pyroxylic spirit, which is reckoned to be a bi-hydrate of *methylen*.

METRICAL MEASURES. The phrase "metrical measures" appears to an ordinary reader to savor of tautology. It is really not so, however, in the present instance; for the expression simply means a set of measures founded on the standard called the "metre," which was adopted by the government of France at the epoch of the first revolution. This standard is the ten-millionth part of the quadrant of the terrestrial meridian, and from the measurements and calculations which were made at that period on an arc of the meridian which extended from Barcelona to Dunkirk, it was reckoned to be 39·371 inches of the English standard yard, which contained 36 inches. Thus the French metre, which is longer than the English yard by $3\frac{1}{4}$ inches, or more accurately by 3·37 inches, is the standard of all the measures and weights of France. Its decimal multiples are successively denoted by the prefixes *deca*, *hecto*, *chilo*, &c., which signify 10, 100, 1000, &c., times respectively; and its decimal sub-multiples or fractions successively by the prefixes *deci*, *centi*, *milli*, &c., which signify $\frac{1}{10}$, $\frac{1}{100}$, $\frac{1}{1000}$, &c., parts respectively. The metre itself was made the unit of lineal measure and itinerary distances.

The *deca* metre squared, which was called the *are*, and consequently contains 100 square metres, was made the unit of superficial or land measure; its centesimal multiple *hectare* contains 10,000 square metres, and its centesimal submultiple *centiare* 1 square metre.

The *decimetre* cubed, which was called the *litre*, and therefore contained a thousandth part of the metre cubed, was made the unit of capacity for liquids; its decimal multiple *decalitre* contains 10 cubic decimetres, and its decimal submultiple *decilitre* one-tenth part of the cubic decimetre. The litre and its successive multiples *decalitre*, *hectolitre*, &c., were also made the measures for dry goods, such as corn, &c. The cubic metre itself was made the unit of solid measures, and called the *stere*; its decimal submultiple the *decistere* containing a tenth part of the cubic metre. The weight of a cubic *centimetre* of distilled water at the maximum density was called the *gramme*, and made the unit of all measures of weight. This unit was found by careful experiments to be equivalent to 15·434 grains of English troy weight; hence the kilogramme, the usual unit for commercial purposes in France, weighs a trifle more than 2·2 pounds of English avoirdupois weight. From the decimal relations which subsist among these different weights and measures, it plainly appears that the *kilogramme* is equal to the weight of a cubic *decimetre* of water, or of a *litre* of the same liquid at the maximum density. The capacity of the *litre* is therefore a trifle more than 61 English cubic inches, or about two-ninths of an English gallon diminished by a hundredth part of the two-ninths.

MICA is a finely foliated mineral, of a pearly metallic lustre. It is harder than gypsum, but not so hard as calc-spar; flexible and elastic; spec. grav. 2·65. It is an ingredient of granite and gneiss. The large sheets of mica exposed for sale in London, are mostly brought from Siberia. They are used, instead of glass, to enclose the fire, without concealing the flame, in certain stoves.

The mica of Fahlun, analyzed by Rose, afforded silica, 46·22; alumina, 34·52; peroxide of iron, 6·04; potash, 8·22; magnesia, with oxide of manganese, 2·11; fluorine acid, 1·09; water, 0·98.

MICROCOSMIC SALT; a term given to a salt extracted from human urine, because man was regarded by the alchemists as a miniature of the world, or the microcosm. It is a phosphate of soda and ammonia; and is now prepared by mixing equivalent proportions of phosphate of soda and phosphate of ammonia, each in solution, evaporating and crystallizing the mixture. A small excess of ammonia aids the crystallization.

MILK; (*Lait*, Fr.; *Milche*, Germ.) owes its whiteness and opacity to an emulsion composed of the caseous matter and butter, with sugar of milk, extractive matters, salts, and free lactic acid; the latter of which causes fresh milk to redden litmus paper. Milk, in general, contains from 10 to 12 per cent. of solid matter, on being evaporated to dryness by a steam heat. The mean specific gravity of cows' milk is 1·030, but it is less if the milk be rich in cream. The specific gravity of the skimmed milk is 1·035; and of the cream is 1·0244. 100 parts of creamed milk contain:—

Caseous matter, containing some butter,	- - - - -	2.600
Sugar of milk,	- - - - -	3.500
Alcoholic extract, lactic acid, and lactates,	- - - - -	0.600
Salts; muriate and phosphate of potash, and phosphate of lime,	- - - - -	0.420
Water,	- - - - -	92.87

Cream consists of—

Butter separated by churning,	- - - - -	4.5
Caseous matter precipitated by the coagulation of the milk of the butter,	- - - - -	3.5
Butter-milk,	- - - - -	93.0

When milk contained in wire-corked bottles is heated to the boiling point in a water-bath, the oxygen of the included small portion of air under the cork seems to be carbonated, and the milk will afterwards keep fresh, it is said, for a year or two; as green gooseberries and peas do by the same treatment.

Milk has been adulterated with a solution of potato starch, from which it derives a creamy consistence. This fraud may be detected by pouring a few drops of iodine water into it, which immediately causes it to assume a blue or purple tint. Emulsion of sweet almonds, with which the milk at Paris has been adulterated, may be readily detected by the taste.

MILL ARCHITECTURE, is a science of recent origin, which even at this day is little understood beyond the factory precincts. It had been ably begun by Mr. Watt, but till it fell into the hands of Messrs. Fairbairn and Lillie, eminent engineers of Manchester, it was too subject to the whims of the several individuals, often utterly ignorant of statics or dynamics, or the laws of equilibrium and impulse, who had capital to lay out in building a mill. Each had his own set of caprices and prejudices, which he sought to embody in his edifice, little aware how much the different orders of machines depended for the productiveness and precision of their performance on the right magnitudes, proportions, and adjustments of the main shafting and wheel gearing. These are in fact the grand nerves and arteries which transmit vitality and volition, so to speak, with due steadiness, delicacy, and speed, to the automatic organs. Hence, if they be ill-made or ill-distributed, nothing can go well.

Mr. Fairbairn has for many years entered largely into the line of a factory architect, for which his three-fold great workshops are admirably adapted. The capitalist has merely to state the extent of his resources, the nature of his manufacture, its intended site and facilities of position in reference to water or coal, when he will be furnished with designs, estimates, and offers on the most economical terms consistent with excellence, according to a plan combining elegance of external aspect with solidity, convenience, and refinement in the internal structure. As engineer, he becomes responsible for the masonry, carpentry, and other work of the building, for the erection of a sufficient power, whether of a steam-engine or water-wheel, to drive every machine it is to contain, and for the mounting of all the shafts and great wheels by which the power of the first mover is distributed.

The recent innovations in proportioning the sizes, regulating the connections, and adjusting the movements of the system of shaft-gearing, form a fine feature in the philosophy of manufactures. Thus not only an improvement has been made in the regularity of impulsion, but a considerable increase of power from the same prime-mover has been obtained; amounting in some cases, of old mills remounted by Messrs. Fairbairn and Lillie, to fully 20 per cent. The durability of shafts so exquisitely turned and polished is another great advantage. The spinning factory of Messrs. Ashworth, at Egerton, which has been at work for several years, exhibits an excellent pattern of the engineering just described: for it has some subordinate shafts, hardly thicker than the human wrist, which convey the power of ten horses, and revolve with great speed, without the slightest noise or vibration. The prime-mover of the whole is a gigantic water-wheel of 60 feet diameter, and 100 horses' power. I have frequently been at a loss in walking through several of the mill-wright factories, to know whether the polished shafts that drive the automatic lathes and planing machines were at rest or in motion, so truly and silently did they revolve.

The method of increased velocities in the driving arms or shafts of factories is undoubtedly one of the most remarkable improvements in practical dynamics. It diminishes greatly the inertia of the mass to be moved, by giving to much lighter shafts and wheels the same momentum; and it permits the pulleys or drums, which immediately impel the machines by straps, to be reduced to a size much nearer to that of the steam pulleys fixed on the main axes of these machines. About thirty years ago the velocities of the main shafts proceeding from the moving power, whether of steam or water, amounted to no more than from 30 to 40 revolutions per minute; and of the smaller and remoter shafts, to only 40 or 50. At the same period the drums were heavy tubs,

and from 30 to upwards of 60 inches in diameter. This improved system is under deep obligations for its actual state of perfection to the above-named engineers, though it had commenced, as we have stated, before their time. In the mills mounted by these gentlemen, it is interesting to see slender shafts, like small sinewy arms, rapidly transmitting vast power through all the ramifications of a great factory.

The following details will place this matter in the clearest light:—A mill propelled by a steam-engine of 50 horses' power, was formerly geared with shafts, having an average transverse section of 36 square inches, or varying in size from 4 to 8 inches square. An engine of like power at the present day will, in consequence of the increased velocities above described, work with cylindrical shafts not exceeding 5½, and often only 3 inches in diameter; possessing, therefore, an average area of only 15 square inches, instead of 36. The horizontal shafts that run under the ceilings of the different working-rooms are 2 inches, and seldom exceed 2½ in diameter. Hence the mass of gearing has been reduced fully one-half. But the shafts now make from 120 to 150 revolutions in a minute, and occasionally, as where throistles are turned, so many as 200 in the same time. Thus we see the requisite momentum is gained with a light shaft, while the friction is proportionally diminished, and the driving-drum revolves with a velocity in accordance with the accelerated pace of the modern machines. The several speeds are given in discussing their respective subjects.

The philosophy of manufactures investigates, in the next place, the most economical and energetic modes of applying the motive force to the various working organs; the carding engines, the drawing heads, the roving frames, the throistles, the mules, the power-looms, the dressing-machines, &c.

The British capitalist is vigorously seconded by the British engineer, and need not, like the continental adventurer, leave his funds long dormant, after an opportunity of placing them profitably in factory enterprise occurs. Fairbairn's millwright establishment in Manchester turns out from 300 to 400 yards of shaft-geering every week, finely finished at a very moderate price, because almost every tool is now more or less automatic, and performs its work more cheaply and with greater precision than the hand could possibly do. Where many counterparts or similar pieces enter into spinning apparatus, they are all made so perfectly identical in form and size, by the self-acting tools, such as the planing and key-grove cutting machines, that any one of them will at once fit into the position of any of its fellows in the general frame.

MILL-STONE, or BUHR-STONE. This interesting form of silica, which occurs in great masses, has a texture essentially cellular, the cells being irregular in number, shape, and size, and are often crossed by thin plates, or coarse fibres of silex. The Buhr-stone has a straight fracture, but it is not so brittle as flint, though its hardness is nearly the same. It is feebly translucent; its colors are pale and dead, of a whitish, grayish, or yellowish cast, sometimes with a tinge of blue.

The Buhr-stones usually occur in beds, which are sometimes continuous, and at others interrupted. These beds are placed amid deposits of sand, or argillaceous and ferruginous marls, which penetrate between them, filling their fissures and honeycomb cavities. Buhr-stones constitute a very rare geological formation, being found in abundance only in the mineral basin of Paris, and a few adjoining districts. Its place of superposition is well ascertained: it forms a part of the lacustrine, or fresh-water formation, which, in the locality alluded to, lies above the fossil-bone gypsum, and the stratum of sand and marine sandstone which covers it. Buhr-stone constitutes, therefore, the uppermost solid stratum of the crust of the globe; for above it there is nothing but alluvial soil, or diluvial gravel, sand, and loam.

Buhr-stones sometimes contain no organic forms, at others they seem as if stuffed full of fresh-water shells, or land shells and vegetables of inland growth. There is no exception known to this arrangement; but the shells have assumed a silicious nature, and their cavities are often bedecked with crystals of quartz. The best Buhr-stones for grinding corn, have about an equal proportion of solid matter, and of vacant space. The finest quarry of them is upon the high ground, near *La Ferté-sous-Jouarre*. The stones are quarried in the open air, and are cut out in cylinders, from one to two yards in diameter, by a series of iron and wooden wedges, gradually but equally inserted. The pieces of buhr-stones are afterwards cut in parallelopipeds, called *panes*, which are bound with iron hoops into large millstones. These pieces are exported chiefly to England and America. Good millstones of a bluish white color, with a regular proportion of cells, when six feet and a half in diameter, fetch 1200 francs a-piece, or 48*l.* sterling. A coarse conglomerate sandstone or breccia is, in some cases, used as a substitute for buhr-stones; but it is a poor one.

MINERAL WATERS. See **SODA WATER**, and **WATERS, MINERAL**.

MINES, (*Bergwerke*, Germ.) Amidst the variety of bodies apparently infinite, which compose the crust of the globe, geologists have demonstrated the prevalence of a few

general systems of rocks, to which they have given the name of *formations* or *deposits*. A large proportion of these mineral systems consists of parallel planes, whose length and breadth greatly exceed their thickness; on which account they are called stratified rocks; others occur in very thick blocks, without any parallel stratification, or horizontal seams of considerable extent.

The stratiform deposits are subdivided into two great classes; the primary and the secondary. The former seem to have been called into existence before the creation of organic matter, because they contain no exuvium of vegetable or animal beings; while the latter are more or less interspersed, and sometimes replete with organic remains. The primary strata are characterized, moreover, by the nearly vertical or highly inclined position of their planes; the secondary lie for the most part in a nearly horizontal position.

Where the primitive mountains graduate down into the plains, rocks of an intermediate character appear, which, though possessing a nearly vertical position, contain a few vestiges of animal beings, especially shells. These have been called *transition*, to indicate their being the passing links between the first and second systems of ancient deposits; they are distinguished by the fractured and cemented texture of their planes, for which reason they are sometimes called conglomerate.

Between these and the truly secondary rocks, another very valuable series is interposed in certain districts of the globe; namely, the coal-measures, the paramount formation of Great Britain. The coal strata are disposed in a basin-form, and alternate with parallel beds of sandstone, slate-clay, iron-stone, and occasionally limestone. Some geologists have called the coal-measures the medial formation.

In every mineral plane, the inclination and direction are to be noted; the former being the angle which it forms with the horizon, the latter the point of the azimuth or horizon, towards which it dips, as west, north-east, south, &c. The direction of the bed is that of a horizontal line drawn in its plane; and which is also denoted by the point of the compass. Since the lines of direction and inclination are at right angles to each other, the first may always be inferred from the second; for when a stratum is said to dip to the east or west, this implies that its direction is north and south.

The smaller sinuosities of the bed are not taken into account, just as the windings of a river are neglected in stating the line of its course.

Masses are mineral deposits, not extensively spread in parallel planes, but irregular heaps, rounded or oval, enveloped in whole or in a great measure by rocks of a different kind. Lenticular masses being frequently placed between two horizontal or inclined strata, have been sometimes supposed to be stratiform themselves, and have been accordingly denominated by the Germans *liegende stocke*, *lying heaps* or *blocks*.

The orbicular masses often occur in the interior of unstratified mountains, or in the bosom of one bed.

Nests, concretions, nodules, are small masses found in the middle of strata; the first being commonly in a friable state; the second often kidney-shaped, or tuberous; the third nearly round, and incrustated, like the kernel of an almond.

Lodes, or large veins, are flattened masses, with their opposite surfaces not parallel, which consequently terminate like a wedge, at a greater or less distance, and do not run parallel with the rocky strata in which they lie, but cross them in a direction not far from the perpendicular; often traversing several different mineral planes. The *lodes* are sometimes deranged in their course, so as to pursue for a little way the space between two contiguous strata; at other times they divide into several branches. The matter which fills the lodes is for the most part entirely different from the rocks they pass through, or at least it possesses peculiar features.

This mode of existence, exhibited by several mineral substances, but which has been long known with regard to metallic ores, suggests the idea of clefts or rents having been made in the stratum posterior to its consolidation, and of the vacancies having been filled with foreign matter, either immediately or after a certain interval. There can be no doubt as to the justness of the first part of the proposition, for there may be observed round many lodes undeniable proofs of the movement or dislocation of the rock; for example, upon each side of the rent, the same strata are no longer situated in the same plane as before, but make greater or smaller angles with it; or the stratum upon one side of the lode is raised considerably above, or depressed considerably below, its counterpart upon the other side. With regard to the manner in which the rent has been filled, different opinions may be entertained. In the lodes which are widest near the surface of the ground, and graduate into a thin wedge below, the foreign matter would seem to have been introduced as into a funnel at the top, and to have carried along with it in its fluid state portions of rounded gravel and organic remains. In other cases, other conceptions seem to be more probable; since many lodes are largest at their under part, and become progressively narrower as they approach the surface; from which circumstance it has been inferred that the rent has been caused by an

expansive force acting from within the earth, and that the foreign matter, having been injected in a fluid state, has afterwards slowly crystallized. This hypothesis accounts much better than the other for most of the phenomena observable in mineral veins, for the alterations of the rock at their sides, for the crystallization of the different substances interspersed in them, for the cavities bestudded with little crystals, and for many minute peculiarities. Thus, the large crystals of certain substances which line the walls of hollow veins, have sometimes their under surfaces besprinkled with small crystals of sulphurets, arseniurets, &c., while their upper surfaces are quite smooth; suggesting the idea of a slow sublimation of these volatile matters from below, by the residual heat, and their condensation upon the under faces of the crystalline bodies, already cooled. This phenomenon affords a strong indication of the igneous origin of metalliferous veins.

In the lodes, the principal matters which fill them are to be distinguished from the accessory substances; the latter being distributed irregularly, amidst the mass of the first, in crystals, nodules, grains, seams, &c. The non-metalliferous exterior portion, which is often the largest, is called *gangue*, from the German *gang*, vein. The position of a vein is denoted, like that of the strata, by the angle of inclination, and the point of the horizon towards which they dip, whence the direction is deduced.

Veins, are merely small lodes, which sometimes traverse the great ones, ramifying in various directions, and in different degrees of tenuity.

A metalliferous substance is said to be *disseminated*, when it is dispersed in crystals, spangles, scales, globules, &c., through a large mineral mass.

Certain ores which contain the metals most indispensable to human necessities, have been treasured up by the Creator in very bountiful deposits; constituting either great masses in rocks of different kinds, or distributed in lodes, veins, nests, concretions, or beds with stony and earthy admixtures; the whole of which become the objects of mineral exploration. These precious stores occur in different stages of the geological formations; but their main portion, after having existed abundantly in the several orders of the primary strata, suddenly cease to be found towards the middle of the secondary. Iron ores are the only ones which continue among the more modern deposits, even so high as the beds immediately beneath the chalk, when they also disappear, or exist merely as coloring matters of the tertiary earthy beds.

The strata of gneiss and mica-slate constitute in Europe the grand metallic domain. There is hardly any kind of ore which does not occur there in sufficient abundance to become the object of mining operations, and many are found nowhere else. The transition rocks, and the lower part of the secondary ones, are not so rich, neither do they contain the same variety of ores. But this order of things, which is presented by Great Britain, Germany, France, Sweden, and Norway, is far from forming a general law; since in equinoctial America the gneiss is but little metalliferous; while the superior strata, such as the clay-schists, the sienitic porphyries, the limestones, which complete the transition series, as also several secondary deposits, include the greater portion of the immense mineral wealth of that region of the globe.

All the substances of which the ordinary metals form the basis, are not equally abundant in nature; a great proportion of the numerous mineral species which figure in our classifications, are mere varieties scattered up and down in the cavities of the great masses or lodes. The workable ores are few in number, being mostly sulphurets, some oxides, and carbonates. These occasionally form of themselves very large masses, but more frequently they are blended with lumps of quartz, feldspar, and carbonate of lime, which form the main body of the deposit; as happens always in proper lodes. The ores in that case are arranged in small layers parallel to the strata of the formation, or in small veins which traverse the rock in all directions, or in nests or concretions stationed irregularly, or finally disseminated in hardly visible particles. These deposits sometimes contain apparently only one species of ore, sometimes several, which must be mined together, as they seem to be of contemporaneous formation; whilst, in other cases, they are separable, having been probably formed at different epochs. In treating of the several metals in their alphabetical order, I have taken care to describe their peculiar geological positions, and the rocks which accompany or mineralize them.

In mining, as in architecture, the best method of imparting instruction is to display the master-pieces of the respective arts, which speak clearly to the mind through the medium of the eye. It is not so easy, however, to represent at once the general effect of a mine, as it is of an edifice; because there is no point of sight from which the former can be sketched at once, like the latter. The subterranean structures certainly afford some of the finest examples of the useful labors of man, continued for ages, under the guidance of science and ingenuity; but, however curious, beautiful, and grand in themselves, they cannot become objects of a panoramic view. It is only by the lights of geometry and geology that mines can be contemplated and surveyed, either as a whole or in their details; and, therefore, these marvellous subterranean regions, in which roads are cut

many hundred miles long, are altogether unknown or disregarded by men of the world. Should any of them, perchance, from curiosity or interest, descend into these dark recesses of the earth, they are prepared to discover only a few insulated objects which they may think strange or possibly hideous; but they cannot recognise either the symmetrical disposition of mineral bodies, or the laws which govern geological phenomena, and serve as sure guides to the skilful miner in his adventurous search. It is by exact plans and sections of subterraneous workings, that a knowledge of the nature, extent, and distribution of mineral wealth can be acquired.

931. *A general view of mining operations.*

As there is no country in the world so truly rich and powerful, by virtue of its mineral stores, as Great Britain, so there are no people who ought to take a deeper interest in their scientific illustration. I have endeavored in the present article to collect from the most authentic sources the most interesting and instructive examples of mining operations.

To the magnificent work of Ville-Fosse, *Sur la Richesse Minérale*, no longer on sale, I have to acknowledge weighty obligations; many of the figures being copied from his great Atlas.

Lodes or mineral veins are usually distinguished by English miners into at least four species. 1. The rake vein. 2. The pipe vein. 3. The flat or dilated vein; and 4. The interlaced mass (*stock-werke*), indicating the union of a multitude of small veins mixed in every possible direction with each other, and with the rock.

1. The rake vein is a perpendicular mineral fissure; and is the form best known among practical miners. It commonly runs in a straight line, beginning at the superficies of the strata, and cutting them downwards, generally further than can be reached. This vein sometimes stands quite perpendicular; but it more usually inclines or hangs over at a greater or smaller angle, or slope, which is called by the miners the *hade* or *hading* of the vein. The line of direction in which the fissure runs, is called the *bearing* of the vein.

2. The pipe vein resembles in many respects a huge irregular cavern, pushing forward into the body of the earth in a sloping direction, under various inclinations, from an angle of a few degrees to the horizon, to a dip of 45°, or more. The pipe does not in general cut the strata across like the rake vein, but insinuates itself between them; so that if the plane of the strata be nearly horizontal, the bearing of the pipe vein will be conformable; but if the strata stand up at a high angle, the pipe shoots down nearly headlong like a shaft. Some pipes are very wide and high, others are very low and narrow, sometimes not larger than a common mine or drift.

3. The flat or dilated vein, is a space or opening between two strata or beds of stone, the one of which lies above, and the other below this vein, like a stratum of coal

between its roof and pavement; so that the vein and the strata are placed in the same plane of inclination. These veins are subject, like coal, to be interrupted, broken, and thrown up or down by slips, dikes, or other interruptions of the regular strata. In the case of a metallic vein, a slip often increases the chance of finding more treasure. Such veins do not preserve the parallelism of their beds, characteristic of coal seams; but vary excessively in thickness within a moderate space. Flat veins occur frequently in limestone, either in a horizontal or declining direction. The flat or strata veins open and close, as the rake veins also do.

4. The interlaced mass has been already defined.

To these may be added the *accumulated vein*, or *irregular mass* (*butzenwerke*), a great deposit placed without any order in the bosom of the rocks, apparently filling up cavernous spaces.

The interlaced masses are more frequent in primitive formations, than in the others; and tin is the ore which most commonly affects this locality. See figure of *Tin mine*.

The study of the mineral substances, called *gangues* or vein-stones, which usually accompany the different ores, is indispensable in the investigation and working of mines. These *gangues*, such as quartz, calcareous spar, fluor spar, heavy spar, &c., and a great number of other substances, although of little or no value in themselves, become of great consequence to the miner, either by pointing out by their presence that of certain useful minerals, or by characterizing in their several associations, different deposits of ores of which it may be possible to follow the traces, and to discriminate the relations, often of a complicated kind, provided we observe assiduously the accompanying *gangues*.

Mineral veins are subject to derangements in their course, which are called *shifts* or *faults*. Thus, when a transverse vein throws out, or intercepts, a longitudinal one, we must commonly look for the rejected vein on the side of the obtuse angle which the direction of the latter makes with that of the former. When a bed of ore is deranged by a fault, we must observe whether the slip of the strata be upwards or downwards; for in either circumstance, it is only by pursuing the direction of the fault that we can recover the ore; in the former case by mounting, in the latter by descending beyond the dislocation.

When two veins intersect each other, the direction of the *offcast* is a subject of interest, both to the miner and the geologist. In Saxony it is considered as a general fact that the portion thrown out is always upon the side of the obtuse angle, a circumstance which holds also in Cornwall; and the more obtuse the angle, the out-throw is the more considerable. A vein may be thrown out on meeting another vein, in a line which approaches either towards its inclination or its direction. The Cornish miners use two different terms to denote these two modes of rejection; for the first case, they say the vein is *beared*; for the second, it is *started*.

The great copper lode of Carharack, *d*, fig. 932, in the parish of Gwenap, is one of the

most instructive examples of intersection. The power or thickness of this vein is 8 feet; its direction is nearly due east and west, and it dips towards the north at an inclination of two feet per fathom; its upper part being in the *killas* (a greenish clay-slate); its lower part in the granite. The lode has suffered two intersections; the first produced by meeting the vein *h*, called *Steven's fluckan*, which runs from north-east to south-west, and which throws the lode several fathoms out; the second is produced by

another vein *i*, almost at right angles with the first, and which occasions another out-throw of 20 fathoms to the right side. The fall of the vein occurs therefore in the one case to the right, and in the other to the left; but in both it is towards the side of the obtuse angle. This distribution is very singular; for one part of the vein appears to have mounted while the other has descended. *N. S.* denotes North and South. *d* is the copper lode running east and west. *h*, *i*, are systems of clay-slate veins called *fluckans*; the line over *s*, represents the down shift, and *d'* the up-shift.

General observations on the localities of ores, and on the indications of metallic mines.

1. *Tin* exists principally in primitive rocks, appearing either in interlaced masses, in beds, or as a constituent part of the rock itself, and more rarely in distinct veins. Tin ore is found indeed sometimes in alluvial land, filling up low situations between lofty mountains.

2. *Gold* occurs either in beds or in veins, frequently in primitive rocks; though in other formations, and particularly in alluvial earth, it is also found. When this metal exists in the bosom of primitive rocks, it is particularly in schists; it is not found in serpentine, but it is met with in graywacke in Transylvania. The gold of alluvial districts,

called gold of washing or transport, occurs, as well as alluvial tin, among the debris of the more ancient rocks.

3. *Silver* is found particularly in veins and beds, in primitive and transition formations; though some veins of this metal occur in secondary strata. The rocks richest in it are: gneiss, mica-slate, clay-slate, graywacke, and old alpine limestone. Localities of silver-ore itself are not numerous, at least in Europe, among secondary formations; but it occurs in combination with the ores of copper or of lead.

4. *Copper* exists in the three mineral epochs; 1. in primitive rocks, principally in the state of pyritous copper, in beds, in masses, or in veins; 2. in transition districts, sometimes in masses, sometimes in veins of copper pyrites; 3. in secondary strata, especially in beds of cupreous schist.

5. *Lead* occurs also in each of the three mineral epochs; abounding particularly in primitive and transition grounds, where it usually constitutes veins, and occasionally beds of sulphureted lead (galena). The same ore is found in strata or in veins among secondary rocks, associated now and then with ochreous iron-oxide and calamine (carbonate of zinc); and it is sometimes disseminated in grains through more recent strata.

6. *Iron* is met with in four different mineral eras, but in different ores. Among primitive rocks, magnetic iron ore and specular iron ore occur chiefly in beds, sometimes of enormous size; the ores of red or brown oxide of iron (hematite) are found generally in veins, or occasionally in masses with sparry iron, both in primitive and transition rocks; as also sometimes in secondary strata; but more frequently in the coal-measure strata, as beds of clay-ironstone, of globular iron oxide, and carbonate of iron. In alluvial districts we find ores of clay-ironstone, granular iron-ore, bog-ore, swamp-ore, and meadow-ore. The iron ores which belong to the primitive period have almost always the metallic aspect, with a richness amounting even to 80 per cent. of iron, while the ores in the posterior formations become in general more and more earthy, down to those in alluvial soils, some of which present the appearance of a common stone, and afford not more than 20 per cent. of metal, though its quality is often excellent.

7. *Mercury* occurs principally among secondary strata, in disseminated masses, along with combustible substances; though the metal is met with occasionally in primitive countries.

8. *Cobalt* belongs to the three mineral epochs; its most abundant deposits are veins in primitive rocks; small veins containing this metal are found, however, in secondary strata.

9. *Antimony* occurs in veins or beds among primitive and transition rocks.

10, 11. Bismuth and nickel do not appear to constitute the predominating substance of any mineral deposits; but they often accompany cobalt.

12. *Zinc* occurs in the three several formations: namely, as sulphuret or blende, particularly in primitive and transition rocks; as calamine, in secondary strata, usually along with oxide of iron, and sometimes with sulphuret of lead.

An acquaintance with the general results collected and classified by geology must be our first guide in the investigation of mines. This enables the observer to judge whether any particular district should, from the nature and arrangement of its rocks, be susceptible of including within its bosom, beds of workable ores; it indicates also, to a certain degree, what substances may probably be met with in a given series of rocks, and what locality these substances will preferably affect. For want of a knowledge of these facts, many persons have gone blindly into researches equally absurd and ruinous.

Formerly, indications of mines were taken from very unimportant circumstances; from thermal waters, the heat of which was gratuitously referred to the decomposition of pyrites; from mineral waters, whose course is however often from a far distant source; from vapors incumbent over particular mountain groups; from the snows melting faster in one mineral district than another; from the different species of forest trees, and from the greater or less vigor of vegetation, &c. In general, all such indications are equally fallacious with the divining rod, and the compass made of a lump of pyrites suspended by a thread.

Geognostic observation has substituted more rational characters of metallic deposits, some of which may be called *negative* and others *positive*.

The *negative* indications are derived from that peculiar geological constitution, which from experience or general principles excludes certain metallic matters; for example, granite, and in general every primitive formation, forbids the hope of finding within them combustible fossils (pit-coal), unless it be beds of anthracite; there also it would be vain to seek for sal gem. It is very seldom that granite rocks include silver; or limestones, ores of tin. Volcanic territories never afford any metallic ores worth the working; nor do extensive veins usually run into secondary and alluvial formations. The richer ores of iron do not occur in secondary strata; and the ores of this metal peculiar to these localities, do not exist among primary rocks.

Among positive indications, some are proximate and others remote. The proximate are, an efflorescence, so to speak, of the subjacent metallic masses; magnetic attraction for iron ores; bituminous stone, or inflammable gas for pit-coal; the frequent occurrence of fragments of particular ores, &c. The remote indications consist in the geological epochs, and nature of the rocks. From the examples previously adduced, marks of this kind acquire new importance when in a district susceptible of including deposits of workable ores, the gangues or vein-stones are met with which usually accompany any particular metal. The general aspect of mountains whose flanks present gentle and continuous slopes, the frequency of sterile veins, the presence of metalliferous sands, the neighborhood of some known locality of an ore, for instance, that of iron-stone in reference to coal, lastly, the existence of salt springs and mineral waters, may furnish some indications; but when ferruginous or cupreous waters issue from sands or clays, such characters merit in general little attention, because the waters may flow from a great distance. No greater importance can be attached to metalliferous sands and saline springs.

In speaking of remote indications, we may remark that in several places, and particularly near Clausthal in the Hartz, a certain ore of red oxide of iron occurs above the most abundant deposits of the ores of lead and silver; whence it has been named by the Germans the *iron-hat*. It appears that the iron ore rich in silver, which is worked in America under the name of *pacos*, has some analogy with this substance; but iron ore is in general so plentifully diffused on the surface of the soil, that its presence can be regarded as only a remote indication, relative to other mineral substances, except in the case of clay iron-stone with coal.

Of the instruments and operations of subterranean operations.—It is by the aid of geometry in the first place that the miner studies the situation of the mineral deposits, on the surface and in the interior of the ground; determines the several relations of the veins and the rocks; and becomes capable of directing the perforations towards a suitable end.

The instruments are, 1. the magnetic compass, which is employed to measure the direction of a metallic ore, wherever the neighborhood of iron does not interfere with its functions; 2. the graduated semi-circle, which serves to measure the inclination, which is also called the clinometer.

3. The chain or cord for measuring the distance of one point from another.

4. When the neighborhood of iron renders the use of the magnet uncertain, a plate or plane table is employed.

The dials of the compasses generally used in the most celebrated mines, are graduated into hours; most commonly into twice 12 hours. Thus the whole limb is divided into 24 spaces, each of which contains $15^\circ = 1$ hour. Each hour is subdivided into 8 parts.

Means of penetrating into the interior of the earth.—In order to penetrate into the interior of the earth, and to extract from it the objects of his toils, the miner has at his disposal several means, which may be divided into three classes; 1. *manual tools*, 2. *gun-powder*, and 3. *fire*.

The tools used by the miners of Cornwall and Devonshire are the following:

Fig. 933. The pick. It is a light tool, and somewhat varied in shape according to cir-

stances. One side used as a hammer is called the *poll*, and is employed to drive in the *gads*, or to loosen and detach prominences. The *point* is of steel, carefully tempered, and drawn under the hammer to the proper form. The French call it *pointierolle*.

Fig. 934. The *gad*. It is a wedge of steel, driven into crevices of rocks, or into small openings made with the point of the pick.

Fig. 935 The *miner's shovel*. It has a pointed form, to enable it to penetrate among the coarse and hard fragments of the mine rubbish. Its handle being somewhat bent, a man's power may be conveniently applied without bending his body.

The *blasting* or *shooting* tools are:—

A sledge or mallet	- - - - -	fig. 936.
Borer	- - - - -	— 937.
Claying bar	- - - - -	— 938.
Needle or nail	- - - - -	— 939.
Scraper	- - - - -	— 940.
Tamping bar	- - - - -	— 941.

Besides these tools the miner requires a powder-horn, rushes to be filled with gunpowder, tin cartridges for occasional use in wet ground, and paper rubbed over with gunpowder or grease, for the *smifts* or fuses.

The *borer*, fig. 937, is an iron bar tipped with steel, formed like a thick chisel, and is used by one man holding it straight in the hole with constant rotation on its axis, while another strikes the head of it with the iron sledge or mallet, fig. 936. The hole is cleared out from time to time by the scraper, fig. 940, which is a flat iron rod turned up at one end. If the ground be very wet, and the hole gets full of mud, it is cleaned out by a stick bent at the end into a fibrous brush, called a *swab-stick*.

Fig. 942 represents the plan of blasting the rock, and a section of a hole ready for

firing. The hole must be rendered as dry as possible, which is effected very simply by filling it partly with tenacious clay, and then driving into it a tapering iron rod, which nearly fills its calibre, called the *claying bar*. This being forced in with great violence, condenses the clay into all the crevices of the rock, and secures the dryness of the hole. Should this plan fail, recourse is had to tin cartridges furnished with a stem or tube, (see fig. 943,) through which the powder may be inflamed. When the hole is dry, and

the charge of powder introduced, the *nail*, a small taper rod of copper, is inserted so as to reach the bottom of the hole, which is now ready for *tamping*. By this difficult and dangerous process, the gunpowder is confined, and the disruptive effect produced. Different substances are employed for *tamping*, or cramming the hole, the most usual one being any soft species of rock free from silicious or flinty particles. Small quantities of it only are introduced at a time, and rammed very hard by the *tamping-bar*, which is held steadily by one man, and struck with a sledge by another. The hole being thus filled, the nail is withdrawn by putting a bar through its eye, and striking it upwards. Thus a small perforation or vent is left for the rush which communicates the fire.

Besides the improved tamping-bar faced with hard copper, other contrivances have been resorted to for diminishing the risk of those dreadful accidents that frequently occur in this operation. Dry sand is sometimes used as a tamping material, but there are many rocks for the blasting of which it is ineffective. Tough clay will answer better in several situations.

For conveying the fire, the large and long green rushes which grow in marshy ground are selected. A slit is made in one side of the rush, along which the sharp end of a bit of stick is drawn, so as to extract the pith, when the skin of the rush closes again by its own elasticity. This tube is filled up with gunpowder, dropped into the vent-hole, and made steady with a bit of clay. A paper *smift*, adjusted to burn a proper time, is then fixed to the top of the rush-tube, and kindled, when the men of the mine retire to a safe distance.

In fig. 942 the portion of the rock which would be dislodged by the explosion, is that included between A and B. The charge of powder is represented by the white part which fills the hole up to C; from which point to the top, the hole is filled with *tamping*. The *smift* is shown at D.

Fig. 944 is an iron bucket, or as it is called in Cornwall, a *kibble*, in which the ore is raised in the shafts, by machines called *whims*, worked by horses. The best kiddles

are made of sheet-iron, and hold each about three hundred weight of ore: 120 kibbles are supposed to clear a cubic fathom of rock.

Fig. 945 represents the wheelbarrow used under ground for conveying ore and waste to the foot of the shafts. It is made of light deal, except the wheel, which has a narrow rim of iron.

Fig. 946 represents Mr. Taylor's ingenious ventilator, or machine for renewing fresh air in mines. It is so simple in construction, so complete in its operation, requires so little power to work it, and is so little liable to injury from wear, that nothing further of the kind can be desired in ordinary metallic mines. The shaft of the mine is represented at A; at either the top or bottom of which the machine may be placed, as is found most convenient, but the foul air must be discharged into a floor, furnished with a valve-door to prevent its return into the mine. *a* is the air-pipe from the mine, passing through the bottom of the fixed vessel or cylinder *c*, which is formed of timber, and bound with iron hoops. It is filled with water nearly to the top of the pipe *a*, on which is fixed a valve opening upwards at *d*. *e*, the air, or exhausting cylinder of cast-iron, open at bottom, and suspended over the air-pipe, but immersed some way in the water. It is furnished with a wooden top, having an aperture fitted with a valve likewise opening upwards at *f*. This exhausting cylinder is moved up and down by the *bob*, *g*, brought into connexion with any engine, by the horizontal rod *h*; the weight of the cylinder being balanced, if necessary, by the counterpoise *i*. The action is as follows:—When the cylinder rises, the air from the mine rushes up through the pipe and valve *d*; and when it descends, this valve shuts, and prevents the return of the air, which is expelled through the valve *f*. With a cylinder two feet in diameter and six feet long, working from two to three strokes per minute, 200 gallons of air may be discharged in the same time.

Gunpowder is the most valuable agent of excavation; possessing a power which has no limit, and which can act everywhere, even under water. Its introduction, in 1615, caused a great revolution in the mining art.

It is employed in mines in different manners, and in different quantities, according to circumstances. In all cases, however, the process resolves itself into boring a hole, and enclosing a cartridge in it, which is afterwards made to explode. The hole is always cylindrical, and is usually made by means of the borer, *fig. 937*, a stem of iron, terminated by a blunt-edged chisel. It sometimes ends in a cross, formed by two chisels set transversely. The workman holds the stem in his left hand, and strikes it with an iron mallet held in his right. He is careful to turn the punch a very little round at every stroke. Several punches are employed in succession, to bore one hole; the first shorter, the latter ones longer, and somewhat thinner. The rubbish is withdrawn as it accumulates, at the bottom of the hole, by means of a picker, which is a small spoon or disc of iron fixed at the end of a slender iron rod. When holes of a large size are to be

made, several men must be employed; one to hold the punch, and one or more to wield the iron mallet. The perforations are seldom less than an inch in diameter, and 18 inches deep; but they are sometimes two inches wide, with a depth of 50 inches.

The gunpowder, when used, is most commonly put up in paper cartridges. Into the side of the cartridge, a small cylindrical spindle or *piercer* is pushed. In this state the cartridge is forced down to the bottom of the hole, which is then stuffed, by means of the tamping bar, *fig. 941*, with bits of dry clay, or friable stones coarsely pounded.* The piercer is now withdrawn, which leaves in its place a channel through which fire may be conveyed to the charge. This is executed either by pouring gunpowder into that passage, or by inserting into it reeds, straw stems, quills, or tubes of paper filled with gunpowder. This is exploded by a long match, which the workmen kindle, and then retire to a place of safety.

As the *piercer* must not only be slender, but stiff, so as to be easily withdrawn when the hole is tamped, iron spindles are usually employed, though they occasionally give rise to sparks, and consequently to dangerous accidents, by their friction against the sides of the hole. Brass piercers have been sometimes tried; but they twist and break too readily.

Each hole bored in a mine, should be so placed in reference to the schistose structure of the rock, and to its natural fissures, as to attack and blow up the least resisting masses. Sometimes the rock is prepared beforehand for splitting in a certain direction, by means of a narrow channel excavated with the small hammer.

The quantity of gunpowder should be proportional to the depth of the hole, and the resistance of the rock, and merely sufficient to split it. Anything additional would serve no other purpose than to throw the fragments about the mine, without increasing the useful effect. Into the holes of about an inch and a quarter diameter, and 18 inches deep, only two ounces of gunpowder are put.

It appears that the effect of the gunpowder may be augmented by leaving an empty space above, in the middle of, or beneath the cartridge. In the mines of Silesia, the consumption of gunpowder has been eventually reduced, without diminishing the product of the blasts, by mixing sawdust with it, in certain proportions. The hole has also been filled up with sand in some cases, according to Mr. Jessop's plan, instead of being packed with stones, which has removed the danger of the tamping operation. The experiments made in this way have given results very advantageous in quarry blasts with great charges of gunpowder; but less favorable in the small charges employed in mines.

Water does not oppose an insurmountable obstacle to the employment of gunpowder; but when the hole cannot be made dry, a cartridge bag impermeable to water must be had recourse to, provided with a tube also impermeable, in which the *piercer* is placed.

After the explosion of each mining charge, wedges and levers are employed, to drag away and break down what has been shattered.

Wherever the rock is tolerably hard, the use of gunpowder is more economical and more rapid than any tool-work, and is therefore always preferred. A gallery, for example, a yard and a half high, and a yard wide, the piercing of which by the hammer formerly cost from five to ten pounds sterling the running yard, in Germany, is executed at the present day by gunpowder at from two to three pounds. When, however, a precious mass of ore is to be detached, when the rock is cavernous, which nearly nullifies the action of gunpowder, or when there is reason to apprehend that the shock caused by the explosion may produce an injurious fall of rubbish, hand-tools alone must be employed.

In certain rocks and ores of extreme hardness, the use both of tools and gunpowder becomes very tedious and costly. Examples to this effect are seen, in the mass of quartz mingled with copper pyrites, worked at Rammelsberg, in the Hartz, in the masses of stanniferous granite of Geyer and Altenberg in the Erzgebirge of Saxony, &c. In these circumstances, fortunately very rare, the action of fire is used with advantage to diminish the cohesion of the rocks and the ores. The employment of this agent is not necessarily restricted to these difficult cases. It was formerly applied very often to the working of hard substances; but the introduction of gunpowder into the mining art, and the increase in the price of wood, occasion fire to be little used as an ordinary means of excavation, except in places where the scantiness of the population has

* Sir Rose Price invented a cap of bronze alloy, to tip the lower end of the iron rod; a contrivance now generally used in Cornwall. Before the Geological Society of that county introduced this invention into practice, scarcely a month elapsed without some dreadful explosion sending the miner to an untimely grave, or so injuring him by blowing out his eyes, or shattering his limbs, as to render him a miserable object of charity for the rest of his days. Scarcely has any accident happened since the employment of the new tamping-bar. When the whole bar was made of the tip and copper alloy it was expensive, and apt to bend; but the iron rod tipped with the bronze is both cheap and effectual. An ingenious instrument, called the shifting cartridge, was invented by Mr. Chinalls, and is described in the Transactions of the above society.

left a great extent of forest timber, as happens at Kongsberg in Norway, at Dannemora in Sweden, at Felsobanya in Transylvania, &c.

The action of fire may be applied to the piercing of a gallery, or to the advancement of a horizontal cut, or to the crumbling down of a mass of ore, by the successive upraising of the roof of a gallery already pierced. In any of these cases, the process consists in forming bonfires, the flame of which is made to play upon the parts to be attacked. All the workmen must be removed from the mine, during, and even for some time after, the combustion. When the excavations have become sufficiently cool to allow them to enter, they break down with levers and wedges, or even by means of gunpowder, the masses which have been rent and altered by the fire.

To complete our account of the manner in which man may penetrate into the interior of the earth, we must point out the form of the excavations that he should make in it.

In mines, three principal species of excavations may be distinguished; viz., *shafts*, *galleries*, and the *cavities* of greater or less magnitude which remain in the room of the old workings.

A *shaft* or *pit* is a prismatic or cylindrical hollow space, the axis of which is either vertical or much inclined to the horizon. The dimension of the pit, which is never less than 32 inches in its narrowest diameter, amounts sometimes to several yards. Its depth may extend to 1000 feet, and more. Whenever a shaft is opened, means must be provided to extract the rubbish which continually tends to accumulate at its bottom, as well as the waters which may percolate down into it; as also to facilitate the descent and ascent of the workmen. For some time a wheel and axle erected over the mouth of the opening, which serve to elevate one or two buckets of proper dimensions, may be sufficient for most of these purposes. But such a machine becomes ere long inadequate. Horse-whims, or powerful steam-engines, must then be had recourse to; and effectual methods of support must be employed to prevent the sides of the shaft from crumbling and falling down.

A *Gallery* is a prismatic space, the straight or winding axis of which does not usually deviate much from the horizontal line. Two principal species are distinguished; the galleries of *elongation*, which follow the direction of a bed or a vein; and the *transverse* galleries, which intersect this direction under an angle not much different from 90°. The most ordinary dimensions of galleries are a yard wide, and two yards high; but many still larger may be seen traversing thick deposits of ore. There are few whose width is less than 24 inches, and height less than 40; such small drifts serve merely as temporary expedients in workings. Some galleries are several leagues in length. We shall describe in the sequel the means which are for the most part necessary to support the roof and the walls. The rubbish is removed by wagons or wheelbarrows of various kinds. See fig. 945

It is impossible to advance the boring of a shaft or gallery beyond a certain rate, because only a limited set of workmen can be made to bear upon it. There are some galleries which have taken more than 30 years to perforate. The only expedient for accelerating the advance of a gallery, is to commence, at several points of the line to be pursued, portions of galleries which may be joined together on their completion.

Whether tools or gunpowder be used in making the excavations, they should be so applied as to render the labor as easy and quick as possible, by disengaging the mass out of the rock at two or three of its faces. The effect of gunpowder, wedges, or picks, is then much more powerful. The greater the excavation, the more important is it to observe this rule. With this intent, the working is disposed in the form of *steps*, (*gradins*), placed like those of a stair; each step being removed in successive portions, the whole of which, except the last, are disengaged on three sides, at the instant of their being attacked.

The substances to be mined occur in the bosom of the earth, under the form of alluvial deposits, beds, pipe-veins, or masses, threads or small veins, and rake-veins.

When the existence of a deposit of ore is merely suspected, without positive proofs, recourse must be had to labors of research, in order to ascertain the richness, nature, and disposition of a supposed mine. These are divided into three kinds; *open workings*, *subterranean workings*, and *boring operations*.

1. The *working by an open trench*, has for its object to discover the outcropping or basest edges of strata or veins. It consists in opening a fosse of greater or less width, which, after removing the vegetable mould, the alluvial deposits, and the matters disintegrated by the atmosphere, discloses the native rocks, and enables us to distinguish the beds which are interposed, as well as the veins that traverse them. The trench ought always to be opened in a direction perpendicular to the line of the supposed deposit. This mode of investigation costs little, but it seldom gives much insight. It is chiefly employed for verifying the existence of a supposed bed or vein.

The *subterranean workings* afford much more satisfactory knowledge. They are executed by different kinds of perforations; viz. by *longitudinal galleries* hollowed out

of the mass of the beds or veins themselves, in following their course; by *transverse galleries*, pushed at right angles to the direction of the veins; by *inclined shafts*, which pursue the slope of the deposits, and are excavated in their mass; or, lastly, by *perpendicular pits*.

If a vein or bed unveils itself on the flank of a mountain, it may be explored, according to the greater or less slope of its inclination, either by a longitudinal gallery opened in its mass, from the outcropping surface, or by a transverse gallery falling upon it in a certain point, from which either an oblong gallery or a sloping shaft may be opened.

If our object be to reconnoitre a highly inclined stratum, or a vein in a level country, we shall obtain it with sufficient precision, by means of shafts, 8 or 10 yards deep, dug at 30 yards distance from one another; excavated in the mass of ore, in the direction of its deposite. If the bed is not very much inclined, only 45° , for example, vertical shafts must be opened in the direction of its roof, or of the superjacent rocky stratum, and galleries must be driven from the points in which they meet the ore, in the line of its direction.

When the rocks which cover valuable minerals are not of very great hardness, as happens generally with the coal formation, with pyritous and aluminous slates, sal gem, and some other minerals of the secondary strata, the *borer* is employed with advantage to ascertain their nature. This mode of investigation is economical, and gives, in such cases, a tolerably exact insight into the riches of the interior. The method of using the borer has been described under *ARTESIAN WELLS*.

OF MINING IN PARTICULAR.

The mode of working mines is two-fold; by *open excavations*, and *subterranean*.

Workings in the open air present few difficulties, and occasion little expense, unless when pushed to a great depth. They are always preferred for working deposits little distant from the surface; where, in fact, other methods cannot be resorted to, if the substance to be raised be covered with incoherent matters. The only rules to be observed are, to arrange the workings in terraces, so as to facilitate the cutting down of the earth; to transport the ores and the rubbish to their destination at the least possible expense; and to guard against the crumbling down of the sides. With the latter view, they ought to have a suitable slope, or to be propped by timbers whenever they are not quite solid.

Open workings are employed for valuable clays, sands, as also for the alluvial soils of diamonds, gold, and oxyde of tin, bog iron ores, &c., limestones, gypsums, building stones, roofing slates, masses of rock salt in some situations, and certain deposits of ores, particularly the specular iron of the island of Elba; the masses of stanniferous granite of *Gayer*, *Altenberg*, and *Seyffen*, in the *Ertzgeberge*, a chain of mountains between Saxony and Bohemia; the thick veins or masses of black oxyde of iron of *Nordmarch*, *Dannemora*, &c., in Sweden; the mass of cupreous pyrites of *Raeraas*, near *Drontheim* in Norway; several mines of iron, copper, and gold in the *Ural mountains*, &c.

Subterranean workings may be conveniently divided into five classes, viz. :—

1. Veins, or beds, much inclined to the horizon, having a thickness of at least two yards.
2. Beds of slight inclination, or nearly horizontal, the power or thickness of which does not exceed two yards.
3. Beds of great thickness, but slightly inclined.
4. Veins, or beds highly inclined, of great thickness.
5. Masses of considerable magnitude in all their dimensions.

Subterranean mining requires two very distinct classes of workings; the *preparatory*, and those for *extraction*.

The *preparatory* consist in galleries, or in pits and galleries destined to conduct the miner to the point most proper for attacking the deposite of ore, for tracing it all round this point, for preparing chambers of excavation, and for concerting measures with a view to the circulation of air, the discharge of waters, and the transport of the extracted minerals.

If the vein or bed in question be placed in a mountain, and if its direction forms a very obtuse angle with the line of the slope, the miner begins by opening in its side, at the lowest possible level, a gallery of elongation, which serves at once to give issue to the waters, to explore the deposite through a considerable extent, and then to follow it in another direction; but to commence the real mining operations, he pierces either shafts or galleries, according to the slope of the deposite, across the first gallery.

For a stratum little inclined to the horizon, placed beneath a plain, the first thing is to pierce two vertical shafts, which are usually made to arrive at two points in the same line of slope, and a gallery is driven to unite them. It is, in the first place, for the sake of circulation of air that these two pits are sunk; one of them, which is also destined for the drainage of the waters, should reach the lowest point of the intended workings.

with gunpowder or with the pick. Should the vein be more than a yard thick, or if its substance be very refractory, two miners are set upon each step. *b b b b* indicate the quadrangular masses that are cut out successively downwards; and 1 1, 2 2, 3 3, forwards; the lines of small circles are the sections of the ends of the billets which support the floors.

2. To attack a mass *v*, fig. 948, a scaffold *m* is erected in one of its terminal pits *p p*,

at the level of the ceiling of the gallery *n n'*, where it terminates below. A miner placed on this scaffold, cuts off at the angle of this mass a parallelopiped 1, from one to two yards high, by six or eight long. When he has advanced thus far, there is placed in the same pit, upon another scaffold *m'*, a second miner, who attacks the vein above the roof of the first cutting, and hews down, above the parallelopiped 1, a parallelopiped of the same dimensions 1', while the first is taking out another 2, in advance of 1. When the second miner has gone forward 6 or 8 yards, a third is placed also in the same pit. He commences the third step, while the first two miners are pushing forwards theirs, and so in succession.

In this mode of working, as well as in the preceding, it is requisite to support the rubbish and the walls of the vein. For the first object, a single floor *n n n*, may be sufficient, constructed above the lower gallery, substantial enough to bear all the rubbish, as well as the miners. In certain cases, an arched roof may be substituted; and in others, several floors are laid at different heights. The sides of the vein are supported by means of pieces of wood fixed between them perpendicularly to their planes. Sometimes, in the middle of the rubbish, small pits are left at regular distances apart, through which the workmen throw the ore coarsely picked, down into the lower gallery. The rubbish occasionally forms a slope *f f f*, so high that miners placed upon it can work conveniently. When the rich portions are so abundant as to leave too little rubbish to make such a sloping platform, the miners plant themselves upon moveable floors, which they carry forward along with the excavations.

These two modes of working in the *step-form*, have peculiar advantages and disadvantages; and each is preferred to the other according to circumstances.

In the *descending workings*, or in *direct steps*, fig. 714, the miner is placed on the very mass or substance of the vein; he works commodiously before him; he is not exposed to the splinters which may fly off from the roof; but by this plan he is obliged to employ a great deal of timber to sustain the rubbish; and the wood is fixed for ever.

In the *ascending workings*, or in *reversed steps*, fig. 715, the miner is compelled to work in the re-entering angle formed between the roof and the front wall of his excavation, a posture sometimes oppressive; but the weight of the ore conspires with his efforts to make it fall. He employs less timber than in the *workings* with *direct steps*. The *sort ing* of the ore is more difficult than in the *descending working*, because the rich ore is sometimes confounded with the heap of rubbish on which it falls.

When seams of diluvium or gravel-mud occur on one of the sides of the vein, or on both, they render the quarrying of the ore more easy, by affording the means of uncovering the mass to be cut down, upon an additional face.

Should the vein be very narrow, it is necessary to remove a portion of the sterile rock which encloses it, in order to give the work a sufficient width to enable the miner to advance. If, in this case, the vein be quite distinct from the rock, the labor may be facilitated, as well as the separation of the ore, by disengaging the vein, on one of its faces, through a certain extent, the rock being attacked separately. This operation is called *stripping the vein*. When it is thus uncovered, a shot of gunpowder is sufficient to detach a great mass of it, unmixed with sterile stones.

By the methods now described, only those parallelopipeds are cut out, either in whole or in part, which present indications of richness adequate to yield a prospect of benefit. In other cases, it is enough to follow out the threads of ore which occur, by workings made in their direction.

The miner, in searching within the crust of the earth for the riches which it conceals, is exposed to many dangers. The rocks amidst which he digs are seldom or never entire, but are almost always traversed by clefts in various directions, so that impending fragments threaten to fall and crush him at every instant. He is even obliged at times to cut through rotten friable rocks or alluvial loams. Fresh atmospheric air follows him with difficulty in the narrow channels which he lays open before him; and the waters which circulate in the subterranean seams and fissures filter incessantly into his excavation, and tend to fill it. Let us now take a view of the means he employs to escape from these three classes of dangers.

1. *Of the timbering of excavations.*—The excavations of mines are divisible into three principal species; *shafts*, *galleries*, and *chambers*. When the width of these excavations is inconsiderable, as is commonly the case with shafts and galleries, their sides can sometimes stand upright of themselves; but more frequently they require to be propped or stayed by billets of wood, or by walls built with bricks or stones; or even by stuffing the space with rubbish. These three kinds of support are called *timbering*, *walling*, and *filling up*.

Timbering is most used. It varies in form for the three species of excavations, according to the solidity of the walls which it is destined to sustain.

In a gallery, for example, it may be sufficient to support merely the roof, by means of joists placed across, bearing at their two ends in the rock; or the roof and the two walls by means of an upper joist *s*, fig. 949, which is then called a *cap* or *cornice beam*,

949

resting on two lateral upright posts or *stanchions*, *a* *b*, to which a slight inclination towards each other is given, so that they approach a little at the top, and rest entirely upon the floor. At times, only one of the walls and the roof need support. This case is of frequent occurrence in pipe veins. Pillars are then set up only on one side, and on the other the joists rest in holes of the rock. It may happen that the floor of the gallery shall not be sufficiently firm to afford a sure foundation to the standards; and it may be necessary to make them rest on a horizontal piece called the *sole*. This is timbering with *complete frames*. The upright posts are usually set directly on the sole; but the extremities of the *cap* or ceiling, and the upper ends of the *standards*, are mortised in such a manner that these cannot come nearer, whereby the cap shall possess its whole force of resistance. In

fractile and shivery rocks there is put behind these beams, both upon the ceiling and the sides, *facing boards*, which are planks placed horizontally, or spars of cleft wood, set so close together as to leave no interval. They are called *fascines* in French. In ordinary ground, the miner puts up these *planks* in proportion as he goes forwards; but in a loose soil, such as sand or gravel, he must mount them a little in advance. He then drives into the mass behind the wooden frame-work, thick but sharp-pointed planks or stakes, and which, in fact, form the sides of the cavity, which he proceeds to excavate. Their one extremity is thus supported by the earth in which it is thrust, and their other end by the last framing. Whenever the miner gets sufficiently on, he sustains the walls by a new frame. The size of the timber, as well as the distance between the frames or *stanchions*, depends on the degree of pressure to be resisted.

When a gallery is to serve at once for several distinct purposes, a greater height is given to it; and a flooring is laid on it at a certain level. If, for example, a gallery is to be employed, both for the transport of the ores and the discharge of the waters, a *floor e e*, fig. 715, is constructed above the bottom, over which the carriages are wheeled, and under which the waters are discharged.

The timbering of shafts varies in form, as well as that of galleries, according to the nature and the locality of the ground which they traverse, and the purposes which they are meant to serve. The shafts intended to be stayed with timber are usually square or rectangular, because this form, in itself more convenient for the miner, renders the execution of the timbering more easy. The wood-work consists generally of rectangular frames, the spars of which are about eight inches in diameter, and placed at a distance asunder of from a yard to a yard and a half. The spars are never placed in contact, except when the pressure of the earth and the waters is very great. The pieces composing the frames are commonly united by a half-check, and the longer of the two pieces extends often beyond the angles, to be rested in the rock. Whether the shaft is vertical or inclined, the frame-work is always placed so that its plane may be perpendicular to the axis of the pit. It happens sometimes in inclined shafts that there are only two sides, or even a single one, which needs to be propped. These are stayed by means of cross beams, which rest at their two ends in the rock. When the frames

do not touch one another, strong planks or stakes are fastened behind them to sustain the ground. To these planks the frames are firmly connected, so that they cannot slide. In this case the whole timbering will be supported, when the lower frame is solidly fixed, or when the pieces from above pass by its angles to be abutted upon the ground.

In the large rectangular shafts, which serve at once for extracting the ores, for the discharge of the waters, and the descent of the workmen, the spaces destined for these several purposes are in general separated by partitions, which also serve to increase the strength of the timberings, by acting as buttresses to the planks in the long sides of the frame-work. Occasionally a partition separates the ascending from the descending basket, to prevent their jostling.—Lastly, particular passages are left for ventilation.

As it is desirable that the wood shall retain its whole force, only those pieces are squared which absolutely require it. The spars of the frames in shafts and galleries are deprived merely of their bark, which by holding moisture, would accelerate the decomposition of the wood. The alburnum of oak is also removed.

Resinous woods, like the pine, last much shorter than the oak, the beech, and the cherry-tree; though the larch is used with advantage. The oak has been known to last upwards of 40 years; while the resinous woods decay frequently in 10. The fresher the air in mines, the more durable is the timbering.

The marginal *figs.* 950, 951 represent two vertical sections of a shaft, the one at right

angles to the other, with excavation by timbering.

951

the view of showing the mode of sustaining the walls of the It is copied from an actual mine in the Hartz. There we may observe the spaces allotted to the descent of the miners by ladders, to the drainage of the waters by pumps *x*, and rods *i*, and to the extraction of the mineral substances by the slides *n*. *a, b, c, f, h, k*, various cross timbers; *A, C, E*, upright do.; *n*, pump cistern; *v, w*, corbe-ways. The shafts here shown, are excavated in the line of the vein itself,—the rock enclosing it being seen in the second figure.

*In a great many mines it is found advantageous to support the excavations by brick or stone buildings, constructed either with or without mortar. These constructions are often more costly than wooden ones, but they last much longer, and need fewer repairs. They are employed instead of timberings, to support the walls and roof of galleries, to line the sides of shafts, and to bear up the roofs of excavations.

Sometimes the two sides of a gallery are lined with vertical walls, and its roof is supported by an ogee vault, or an arch. If the sides of the mine are solid, a simple arch is

sufficient to sustain the roof, and at other times the whole surface of a gallery is formed of a single elliptic vault, the great axis of which is vertical; and the bottom is surmounted by a wooden plank, under which the waters run off; see *fig.* 951.

Walled shafts also are sometimes constructed in a circular or elliptic form, which is better adapted to resist the pressure of the earth and waters. Rectangular shafts of all dimensions, however, are frequently walled.

The sides of an excavation may also be supported by filling it completely with rubbish. Wherever the sides need to be supported for some time without the necessity of passing along them, it is often more economical to stuff them up with rubbish, than to keep up their supports. In the territory of Liege, for example, there have been shafts thus filled up for several centuries; and which are found to be quite entire when they are emptied. The rubbish is also useful for forming roads among steep strata, for closing air-holes, and forming canals of ventilation.

Figs. 952, 953, 954 represent the principal kinds of mason-work employed in the galleries and shafts of mines. *Fig.* 955 exhibits the walling in of the cage of an over-shot water wheel, as mounted within a mine. Before beginning to build, an exca-

wheel, *e, g*, double crank with rods, whose motion is taken off the left side of the wheel; *a, d*, the same upon the right side. The distance from *h* to *f* is about 22 yards.

Figs. 956, 957 present two vertical sections of the shaft of a mine walled, like the roof of a cavern, communicating with the galleries of the roof and the wall of the vein, and well arranged for both the extraction of the ore, and the descent of the miners. The vertical partition of the shaft for separating the passage for the corves or tubs from the ladders is omitted in the figure, for the sake of clearness.

In fig. 956, *A, B* are the side walls supported upon the buttresses *c* and *D*; in fig. 957, *E* is the masonry of the wall, borne upon the arch *F* at the entrance to a gallery; the continuation being at *G*, which is sustained by a similar arch built lower.

L, is the vault arch of the roof, supported upon another vault *M*, which presents a double curvature, at the entrance of a gallery; at *H* is the continuation of the arch or vault *L*, which underneath is supported in like manner at the entrance of a lower gallery.

a b, c d, fig. 956, are small upright guide-bars or rods for one of the corves, or kibbles.

e f, g h, are similar guide-bars for the other corf.

i i, are cross-bars of wood, which support the stays of the ladders of descent.

k k, are also cross-bars by which the guide-rods are secured.

l, a corf, or extraction kibble, furnished with friction rollers; the other corf is supposed to be drawn up to a higher level, in the other vertical passage.

Figs. 958, 959 represent in a vertical section the mode of timbering the galleries of the silver and lead mines at Andreasberg in the Hartz. Fig. 958 shows the plan viewed from above. Upon the roof of the timbering, the workman throws the waste rubbish, and in the empty space below, which is shaded black, he transports in his wagons or wheelbarrows the ores towards the mouth of the mine. Fig. 959 is the cross section of the gallery. In the two figures, *a* represents the rock, and *b* the timbering; round which there is a garniture of small spars or lathes for the purpose of drainage and ventilation, with the view of promoting the durability of the wood-work.

The working of minerals by the *mass* is well exemplified a few leagues to the north of Siegen, near the village of Müsen, in a mine of iron and other metals, called *Stahlberg*, which forms the main wealth of the country. The plan of working is termed the *excavation of a direct or transverse mass*. It shows in its upper part the danger of bad mining, and in its inferior portion, the regular workings, by whose means it has eventually prevented the destruction of a precious mineral deposit.

Fig. 960 is a vertical section of the bed of ore, which is a *direct mass of spathose*

iron, contained in transition rock (graywacke). *a, a, a,* are pillars of the sparry ore, reserved to support the successive stages or floors, which are numbered 1, 2, 3, &c.; *b, b, b,* are excavations worked in the ore; which exhibit at the present day several floors of arches, of greater or less magnitude, according to the localities. It may be remarked, that where the metallic deposit forms one entire mass, rich in spathose iron ore of good quality, there is generally given to the vaults a height of three fathoms; leaving a thickness over the roof of two fathoms, on account of the numerous fissures which pervade the mass. But where this mass is divided into three principal branches, the roof of the vaults has only a fathom and a half of thickness, while the excavation is three fathoms and a half high. In the actual state of the workings, it may be estimated that from all this direct mass, there is obtained no more out of every floor than one third of the mineral. Two thirds remain as labors of reserve, which may be resumed at some future day, in consequence of the regularity and the continuation of the subterranean workings. *e* is a shaft for extraction, communicating below with the gallery of efflux *k*; *h* is an upper gallery of drainage, which runs in different directions (one only being visible in this section) over a length of 400 fathoms. The lower gallery *k* runs 646 fathoms in a straight line. The mine of Stahlberg has furnished annually on an average since 1760 about 25,000 cubic feet (French) of an excellent spathose ore of iron. *m m*, represents the mass of sparry iron.

Figs. 961, 962, 963 represent the cross system of mining, which consists in forming galleries through a mineral deposit, from its wall or floor towards its roof, and not, as usual, in the direction of its length. This mode was contrived towards the middle of the 18th century, for working the very thick veins of the Schemnitz mine in Hungary, and it is now employed with advantage in many places, particularly at Idria in Carniola. In the two sections figs. 961, 963, as well as in the ground plan fig. 962, the wall is denoted by *m m*, and the roof by *t t*. A first gallery of prolongation *ε ε*, fig. 963, being formed to

the wall, transverse cuts, *a a*, are next established at right angles to this gallery, so that between every two there may be room enough to place three others, *b, c, b*, fig. 962. From each of the cuts *a*, ore is procured by advancing with the help of timbering, till the roof *t* is reached. When this is done, these first cuts *a*, are filled up with rubbish, laid upon pieces of timber with which the ground is covered, so that if eventually it should be wished to mine underneath, no downfall of detritus is to be feared. These heaps of rubbish rise only to within a few inches of the top of the cuts *a*, in order that the working of the upper story may be easier, the bed of ore being there already laid open upon its lower face.

In proportion as the cuts *a*, of the first story *ε ε*, are thus filled up, the greater part of the timbering is withdrawn, and made use of elsewhere. The intermediate cuts *b, c, b*, are next mined in like manner, either beginning with the cuts *c*, or the cuts *b*, according to the localities. From fig. 962 it appears that the working may be so arranged, that in case of necessity, there may be always between two cuts in activity the

distance of three cuts, either not made, or filled up with rubbish. Hence, all the portion of the bed of ore may be removed, which corresponds to a first story *E F*, *fig. 963*, and this portion is replaced by rubbish.

The exploration of the upper stories *E' F'*, *E² F²*, *E³ F³*, is now prepared in a similar manner; with which view shafts *h h*, *k k*, are formed from below upwards in the wall *m* of the deposite, and from these shafts oblong galleries proceed, established successively on a level with the stories thus raised over one another. See *fig. 963*. The following objects may be specified in the figures:—

- a a*, the first cuts filled up with rubbish, upon the first story *E F*, *fig. 962*.
- b b*, other cuts subsequently filled up, upon the same story.
- c*, the cut actually working.
- d*, the front of the cut, or place of actual excavation of the mineral deposite.
- e*, masses of the barren rock, reserved in the cutting, as pillars of safety.
- f*, galleries, by means of which the workmen may turn round the mass *e*, in order to form, in the roof *t*, an excavation in the direction of the deposite.
- g*, rubbish behind the mass *e*.
- h h*, two shafts leading from the first story *E F*, to the upper stories of the workings, as already stated.
- m*, the wall, and *t* the roof of the mineral bed.

In the second story *E' F'*, the gallery of prolongation *F'*, *figs. 961* and *963*, is not entirely perforated; but it is further advanced than that of the third story, which, in its turn, is more than the gallery of the fourth.

From this arrangement there is produced upon *fig. 963* the general aspect of a working by reversed steps.

Whenever the workings of the cuts *c* in the first story are finished, those of the second, *a' a'*, may be begun in the second; and thus by mounting from story to story, the whole deposite of ore may be taken out and replaced with rubbish. One great advantage of this method is, that nothing is lost; but it is not the only one. The facilities offered by the system of *cross workings* for disposing of the rubbish, most frequently a nuisance to the miner, and expensive to get rid of, the solidity which it procures by the banking up, the consequent economy of timbering, and saving of expense in the excavation of the rock, reckoning from the second story, are so many important circumstances which recommend this mode of mining. Sometimes, indeed, rubbish may be wanted to fill up, but this may always be procured by a few accessory perforations; it being easy to establish in the vicinity of the workings a vast excavation in the form of a vault, or kind of subterraneous quarry, which may be allowed to fall in with proper precautions, and where rubbish will thus accumulate in a short time, at little cost.

Fig. 964 represents a section of the celebrated lead mines of Bleyberg in Carinthia, not far from Villach.

b, c, is the ridge of the mountains of compact limestone, in whose bosom the workings are carried on.

e is the metalliferous valley, running from east to west, between the two parallel

valleys of the Gail and the Drave, but at a level considerably above the waters of these rivers.

f g is the direction of a great many vertical beds of metalliferous limestone.

On considering the direction and dip of the marly schist, and metalliferous limestone,

in the space *w, w*, to the west of the line *1, s*, it would appear that a great portion of this system of mountains has suffered a slip between *1, s*, and a parallel one towards the east; whereby, probably, that vertical position of the strata has been produced, which exists through a considerable extent. The metalliferous limestone is covered to a certain thickness with a marly schist, and other more recent rocks. It is in this schist that the fine marble known under the name of the *lumachello* of Bleyberg is quarried.

The galena occurs in the bosom of this rock in flattened masses, or blocks of a considerable volume, which are not separated from the rest of the calcareous beds by any seam. It is accompanied by zinc ore (*calamine*), especially in the upper parts of the mountain.

Several of the workable masses are indicated by *r, r3*; each presents itself as a solid analogous to a very elongated ellipse, whose axis dips, not according to the inclination of the surrounding rock, but to an oblique or intermediate line between this inclination, and the direction of the beds of limestone; as shown by *r w, r' u*. Every thing indicates the contemporaneous formation of the limestone, and the lying beds of the lead ore.

The accidents or faults called *kluft* (*rent*) at Bleyberg are visible on the surface of the ground. Experienced miners have remarked that the rich masses occur more frequently in the direction of these accidents than elsewhere.

It is in general by galleries cut horizontally in the body of the mountain, and at different levels, *s, g, sf*, that the miner advances towards the masses of ore *r, r3*. Many of these galleries are 500 fathoms long before they reach a workable mass. The several galleries are placed in communication by a few shafts, such as *t*; but few of these are sunk deeper than the level of the valley *e*.

The total length of the mines of Bleyberg is about 10,000 yards, parallel to the valley *e*; in which space there are 500 concessions granted by the government to various individuals or joint stock societies, either by themselves or associated with the government.

The metalliferous valley contains 5000 inhabitants, all deriving subsistence from the mines; 300 of whom are occupied in the government works.

Each concession has a number and a name; as Antoni, Christoph, Matthæus, Oswaldi, 2, 8, 36, &c.

Fig. 965 is a section in the quicksilver mine of Idria. 1. is the gray limestone; 2. is a blackish slate; 5. is a grayish slate. Immediately above these transition rocks lies the bed containing the ores called *corallenerz*, which consist of an intimate mixture of sulphuret of mercury and argillaceous limestone; in which four men can cut out, in a month, 24 *tolises* cube of rock.

Fig. 966 represents a section of part of the copper mine of Mansfeldt; containing the cellular limestone, called *rauchwacke*, always with the compact marl-limestone called *zechstein*; the cupreous schist, or *kupferschiefer*; the wall of grayish-white sandstone, called the *weisse liegende*; and the wall of red sandstone, or the *rothelie gende*. The thin dotted stratum at top is vegetable mould; the large dotted portion to the right of the figure is oolite; the

vein at its side is sand; next is *rauchwacke*; and lastly, the main body of fetid limestone, or *stinkstein*.

Fig. 967 represents one of the Mansfeldt copper schist mines in the district called Burgoerner, or Preussshohheit.

1. Vegetable mould, with silicious gravel.
2. Ferruginous clay or loam.
3. Sand, with fragments of quartz.
4. Red clay, a bed of variable thickness as well as the lower strata, according as the cupreous schist is nearer or farther from the surface.
5. Oolite (*roogenstein*).
6. Newer variegated sandstone (*bunter sandstein*).
7. Newer gypsum; below which, there is
8. A bluish marly clay.
9. Stinkstone, or lucullite.
10. Friable grayish marl.
11. Older gypsum, a rock totally wanting in the other districts of the mines of Rothenberg; but abounding in Saxon Mansfeldt, where it includes vast caverns known among the miners by the name of *schlotten*, as indicated in the figure.

12. The calcareous rock called *zechstein*. The lower part of this stratum shows symptoms of the cupriferous schist that lies underneath. It presents three thin bands, differently modified, which the miner distinguishes as he descends by the names of the sterile or rotten (*faule*) rock; the roof (*dachklotz*); and the main rock (*oberberg*.)

13. Is a bed of cupriferous schist (*kupferschiefer*), also called the *bitumino-marly* schist, in which may be noted, in going down, but not marked in the figure:—

- a, the *lochberg*, a seam 4 inches thick.
- b, the *kammschale*, $\frac{1}{4}$ of an inch thick.
- c, the *kopfschale*, one inch thick.

These seams are not worth smelting; the following, however, are:—

- d, the *schiefer kopf*, the main copper schist, 2 inches thick.
- e, a layer called *lochen*, one inch thick.

14. The wall of sandstone, resting upon a porphyry.

Fig. 968 is a section of the mines of Kiegelsdorf in Hessa, presenting—

1. Vegetable mould.
2. Limestone distinctly stratified, frequently of a yellowish color, called *lagerhafter kalkstein*.
3. Clay, sometimes red, sometimes blue, sometimes a mixture of red, blue, and yellow.
4. The cellular limestone (*rauhkalk*). This rock differs both in nature and position from the rock of the same name at Mansfeldt.
5. Clay, usually red, containing veins of white gypsum, and fine crystals of selenite.
6. Massive gypsum of recent formation.
7. Fetid limestone, compact and blackish gray, or cellular and yellowish gray.
8. Pulverulent limestone, with solid fragments interspersed.
9. Compact marl-limestone, or *zechstein*, which changes from a brownish color above to a blackish schist below, as it comes nearer the cupreous schist, which seems to form a part of it.
10. Cupreous schist (*kupferschiefer*), of which the bottom portion, from 4 to 6 inches thick, is that selected for metallurgic operations. Beneath it, is found the usual wall or bed of sandstone. A vein of cobalt ore a, which is rich only in the grayish-white sandstone (*weisse liegende*), traverses and deranges all the beds wherever it comes.

Of working mines by fire.—The celebrated mine worked since the tenth century in the mountain called *Rammelsberg*, in the Hartz, to the south of Goslar, presents a stra-

tified mass of ores, among the beds of the rock which constitute that mountain. The mineral deposit is situated in the earth, like an enormous inverted wedge, so that its thickness (power), inconsiderable near the surface of the ground, increases as it descends. At about 100 yards from its outcrop, reckoning in the direction of the slope of the deposit, it is divided into two portions or branches, which are separated from each other, throughout the whole known depth, by a mass of very hard clay slate, which passes into flinty slate. The substances composing the workable mass are copper and iron pyrites with sulphuret of lead (galena), accompanied by quartz, carbonate of lime, compact sulphate of baryta, and sometimes gray copper ore, sulphuret of zinc, and arsenical pyrites. The ores of lead and copper contain silver and gold, but in small proportion, particularly as to the last.

A mine so ancient as that of Rammelsberg, and which was formerly divided among several adventurous companies, cannot fail to present a great many shafts and excavations; but out of the 15 pits, only two are employed for the present workings; namely, those marked *A B* and *E F*, in *fig. 969*, by which the whole extraction and drainage are

executed. The general system of exploitation by fire, as practised in this mine, consists of the following operations:—

1. An advance is made towards the deposits of ore, successively at different levels, by transverse galleries which proceed from the shaft of extraction, and terminate at the wall of the stratiform mass.
2. There is formed in the level to be worked, large vaults in the heart of the ore, by means of fire, as we shall presently describe.
3. The floor of these vaults is raised up by means of terraces formed from the rubbish, in proportion as the roof is scooped out.
4. The ores detached by the fire from their bed, are picked and gathered; sometimes the larger blocks are blasted with gunpowder.
5. Lastly, the ores thus obtained are wheeled towards the shaft of extraction, and turned out to the day.

Let us now see how the excavation by fire is practised; and in that view, let us consider the state of the workings in the mines of Rammelsberg in 1809. We may remark in *fig. 969* the regularity of the vaults previously scooped out above the level *bc*, and the other vaults which are in full activity of operation. It is, therefore, towards the lower levels that the new workings must be directed. For this purpose, the transverse gallery being already completed, there is prepared on the first of these floors a vault of exploitation at *b*, which eventually is to become similar to those of the superior levels. At the same time, there is commenced at the starting point below it, reached by a small well dug in the line of the mineral deposit, a transverse gallery in the rock, by means of blasting with gunpowder. The rock is also attacked at the starting-point by a similar cut, which advances to meet the first perforation. In this way, whenever the vaults of the level *c* are exhausted of ore and terraced up with rubbish, those of the level beneath it will be in full activity.

Others will then be prepared at a lower level; and the exploitation may afterwards be driven below this level by pursuing the same plan, by which the actual depth of excavation has been gained.

In workings by fire we must distinguish, 1. The case where it is necessary to open a vault immediately from the floor; 2. The case where the vault having already a certain elevation, it is necessary to heighten its roof. In the former case, the wall or floor of the mineral deposit is first penetrated by blasting with gunpowder. As soon as this penetration is effected over a certain length, parallel to the direction of the future vault, as happens at *b*, there is arranged on the bottom a horizontal layer of billets of firwood, over which other billets are piled in nearly a vertical position, which rest upon the ore, so that the flame in its expansion comes to play against the mineral mass to be

detached. When after some similar operations, the flame of the pile can no longer reach the ore of the roof on account of its height, a small terrace of rubbish must be raised on the floor of the deposit; and over this terrace, a new pile of fagots is to be heaped up as above described. The ancient miners committed the fault of constantly placing such terraces close to the roof, and consequently arranging the fagots against this portion of the ore, so that the flame circulated from the roof down to the floor. The result of such procedure was the weakening of the roof, and the loss of much of the ore which could not be extracted from so unstable a fabric; and besides, much more wood was burned than at the present day, because the action of the flame was dissipated in part against the whole mass of the roof, instead of being concentrated on the portion of the ore which it was desired to dislodge. Now, the flame is usually made to circulate from the floor to the roof, in commencing a new vault.

When the vault has already a certain height, care is always taken that between the roof of the vault and the rubbish on which the pile is arranged, no more than two yards of space should intervene, in order that the flame may embrace equally the whole concavity of the vault, and produce a uniform effect on all its parts. Here, the pile is formed of horizontal beds, disposed crosswise above one another, and presents four free vertical faces, whence it has been called a *chest* by the miners.

It is usually on Saturday that the fire is applied to all the piles of fagots distributed through the course of the week. Those in the upper floors of exploitation are first burned, in order that the inferior piles may not obstruct, by their vitiated air, the combustion of the former. Thus, at 4 o'clock in the morning, the fires are kindled in the upper ranges; from pile to pile, the fireman and his assistant descend towards the lower floors, which occupies them till 3 o'clock in the afternoon. Vainly should we endeavor to describe the majestic and terrific spectacle which the fire presents, as it unfolds its wings under its metallic vaults, soon filled with vast volumes of smoke and flame. Let us mark the useful effect which it produces.

When the flame has beat for a few instants on the beds of ore, a strong odor of sulphur, and sometimes of arsenic is perceived; and soon thereafter loud detonations are heard in the vaults. Suddenly the flame is seen to assume a blue color, or even a white; and at this period, after a slight explosion, flakes of the ore, of greater or less magnitude, usually fall down on the fire, but the chief portion of the heated mineral still remains fixed to the vault. The ores pass now into a shattered and divided condition, which allows them afterwards to be detached by long forks of iron. In this manner the fire, volatilizing entirely some principles, such as sulphur, zinc, arsenic, and water, changing the aggregation of the constituent parts of the ore, and causing fissures by their unequal expansibilities, facilitates the excavation of such materials as resist by their tenacity the action of gunpowder.

The combustion goes on without any person entering the mine from Saturday evening till Monday morning, on which day, the fireman and his assistants proceed to extinguish the remains of the bonfires. On Monday also some piles are constructed in the parts where the effect of the former ones has been incomplete; and they are kindled after the workmen have quitted the mine. On Tuesday all hands are employed in detaching the ores, in sorting them, taking them out, and preparing new piles against the next Saturday.

The labor of a week consists for every man of five posts during the day, each of 8 hours, and of one post of four hours for Saturday. Moreover, an extra allowance is made to such workmen as employ themselves some posts during the night.

The labor of one compartment or *atelier* of the mine consists therefore in arranging the fagots, in detaching the ore which has already experienced the action of the fire, in breaking the blocks obtained, in separating the ore from the *debris* of the pile, and, whenever it may be practicable or useful, in boring holes for blasting with gunpowder. The heat is so great in this kind of mine, that the men are obliged to work in it without clothing.

We have already remarked, that besides the working by fire, which is chiefly used here, recourse is sometimes had to blasting by gunpowder. This is done in order either to recover the bottom part or ground of the vaults on which the fire can act but imperfectly, to clear away some projections which would interfere with the effect of the pile, or lastly to strip the surrounding rock from the mass of the ore, and thence to obtain schist proper for the construction of the rubbish-terraces.

The blasting process is employed when the foremen of the workshop or mine-chamber judge that a hole well placed may separate enough of ore to pay the time, the repair of tools, and the gunpowder expended. But this indemnification is rarely obtained. The following statement will give an idea of the tenacity which the mineral deposit often presents.

In 1808, in a portion of the Rammelsberg mine, the ore, consisting of extremely compact iron and copper pyrites, was attacked by a single man, who bored a mining hole.

After 11 posts of obstinate labor, occupying altogether 88 hours, the workman, being vigilantly superintended, had been able to advance the hole to a depth of no more than 4 inches; in doing which he had rendered entirely unserviceable 126 punches or borers, besides 26 others which had been re-tipped with steel, and 201 which had been sharpened; 6½ pounds of oil had been consumed in giving him light; and half a pound of gunpowder was required for blasting the bore. It was found from a calculation made upon these facts by the administration of mines, that every inch deep of this hole cost, at their low price of labor, nearly a florin, value two shillings and sixpence.

It is therefore evident that though the timber, of which the consumption is prodigiously great, were much less abundant and dearer than it still is at Rammelsberg, mining by fire would be preferable to every other mode of exploitation. It is even certain, that on any supposition, the employment of gunpowder would not be practicable for every part of the mine; and if fuel came to fail, it would be requisite to renounce the workings at Rammelsberg, although this mountain still contains a large quantity of metals.

If in all mines the free circulation of air be an object of the highest importance, we must perceive how indispensable it must be in every part of a mine where the mode of exploitation maintains the temperature of the air at 112° Fahr., when the workmen return into it after the combustion of the piles, and in which besides it is necessary that this combustion be effected with activity in their absence. But in consequence of the extent and mutual ramifications of the workings, the number of the shafts, galleries, and their differences of level, the ventilation of the mine is in a manner spontaneously maintained. The high temperature is peculiarly favorable to it. The aid of art consists merely in placing some doors judiciously, which may be opened or shut at pleasure, to carry on the circulation of the air.

In considering the Rammelsberg from its summit, which rises about 400 yards above the town of Goslar, we observe, first, beds of slaty sandstone, which become the more horizontal the nearer they approach to the surface. At about 160 yards below the top level there occurs, in the bosom of the slaty graywacke, a powerful stratum of shells impasted in a ferruginous sandstone. See *D*, fig. 963. In descending towards the

face of the ore, the parallel stratification of the clay-slate which forms its walls and roof grows more and more manifest. Here the slate is black, compact, and thinly foliated. The inclination of the different beds of rock is indicated at *n*. The substance of the workable mass is copper and iron pyrites, along with sulphuret of lead, accompanied by quartz, carbonate of lime, compact sulphate of baryta, and occasionally gray copper (*fahlerz*), sulphuret of zinc, and arsenical pyrites.

The ores are argentiferous and auriferous, but very slightly so, especially as to the gold. It is the ores of lead and copper which contain the silver, and in the latter the gold is found, but without its being well ascertained in what mineral it is deposited. Sometimes the copper occurs in the native state, or as copper of cementation. Beautiful crystals of sulphate of lime are found in the old workings.

In figs. 969, 970, *A N* is the shaft of extraction, called the *Kahnenkuhler*; *N* is the ventilation shaft, called *Breitlingerwetterschacht*; *P* is the extraction shaft, called *Innerschacht*.

E P, is a new extraction-shaft, called *Neuer treibschacht*, by which also the water is pumped up; by *A B*, and *E P*, the whole extraction and draining are carried on. The ores are raised in these shafts to the level of the wagon-gallery (*galerie de roulage*) *i*, by the whims 1, *q*, provided with ropes and buckets. 1, 2, 3, 4, fig. 969, represent the positions of four water-wheels for working the whims; the first two being employed in extracting the ores, the last two in draining. The driving stream is led to the wheel 1, along the drift *l*; whence it falls in succession

upon the wheels 2, 3, 4. The general system of working consists of the following operation:—

1. The bed of ore is got at by the transverse galleries, *m*, *n*, *o*, *q*, *a*, *s*, which branch off from the extraction shaft, and terminate at the wall of the main bed;

2. Great vaults are scooped out at the level of the workings, by means of fire;

2. Great vaults are scooped out at the level of the workings, by means of fire;
3. The roofs of these vaults are progressively propped with mounds of rubbish;
4. The ores thus detached, or by blasting with gunpowder, are then collected;
5. Lastly, they are wheeled out to the day; and washed near z.

COMPARATIVE TABLE of celebrated MINES in EUROPE and AMERICA. By F. Burr, Esq
(Quarterly Mining Review for July, 1835, p. 60.)

	CONSOLIDATED AND UNITED MINES. (At present the richest mines in Cornwall.)	VETA GRANDE MINES. (At present the richest mines in Mexico.)	MINE OF VALENCIANA. (Richest of the Mexican mines at the beginning of the present century.)	MINE OF HUMBOLDT. (Richest of the Mexican mines at the beginning of the present century.)
Situation	Two miles east of Redruth.	Four miles north of Zaca-tecas.	One mile north of Guanaxuato.	Two miles south-east of Freiberg.
Elevation	Elevation of the surface above the level of the sea, from 500 to 300 ft.; depth of the bottom of the mine below the level of the sea, about 1,370 feet.	Elevation of the surface above the level of the sea, supposed to be about 6000 feet. Elevation of the bottom of the mine above the level of the sea, probably near 5,000 feet.	Elevation of the surface above the level of the sea, 7,517 feet. Elevation of the bottom of the mine above the level of the sea, 5,730 feet.	Elevation of the surface above the level of the sea, 1,346 feet. Elevation of the bottom of the mine above the level of the sea, 263 feet.
Nature of the rock	Primary clay slate resting immediately on granite, a short distance westward of the mines. The clay slate is intersected by numerous channels of porphyry, which have nearly the same direction as the mineral veins, and are often of considerable width. The porphyry sometimes appears also to form large irregular masses in the clay slate. Both rocks are traversed by veins of quartz and clay intersecting the metalliferous veins.	Transition clay slate, alternating with dolomite, and occasionally with greywacke. This clay slate is sometimes decomposed; it rests on syenitic rocks, and is in some places covered with porphyry.	The <i>Peto Madre</i> of Guanaxuato, upon which this mine is worked, traverses both clay slate and porphyry, but it is most productive in the former rock. The clay slate is considered by Humboldt to belong to the transition class, but sitsuate near the limits of primary formations. This rock in depth passes into chlorite slate, and talc slate. It contains subordinate beds of syenite, hornblende slate, and serpentine. The porphyry rests upon the clay slate, and is conformable to it, both in direction and stratification.	The rock prevailing in the neighbourhood of Freiberg, in which this and most of the other mines are situate, is a formation of primary gneiss.
Nature of the metalliferous deposits	In the consolidated mines, the eight following lodes are extensively worked:—Wheel Fortune lode, Cuvea lode, Deeble's lode, Old lode, Taylor's lode, Tregunning's lode, Martin's lode, and Glover's lode. In the united mines, the principal workings are upon the Old lode, and about five or six others are more or less productive. Numerous smaller lodes or "branches" occur also in both mines. The principal lodes are from 2 or 3, to 7 or 8 feet wide; the "branches" are generally 12 or 18 inches wide. The direction of the lodes varies from nearly east and west to about 30 degrees north of east and south of west. The underlie of the principal lodes is from 2 to 3 feet per fathom north, that of the smaller ones about the same south.	One principal veta (the <i>Veta Grande</i>) which is generally separated into three branches, and sometimes into four. When ramified, the width extends to 60 or 70 feet; when united, it varies from 5 or 10 to 20 or 30 feet. The branches are generally about 10 or 12 feet wide; and the upper one is most productive. The direction of the <i>Veta Grande</i> is from 30 to 40 degrees south of east, and north of west, and its underlie, from two to three feet per fathom south. Other veins of less size occur in the neighbourhood of the <i>Veta Grande</i> , which cross it at an acute angle. One of these appears to heave the vein for about 700 feet, being the most remarkable derangement of the kind on record.	One <i>Veta</i> (the <i>Peto Madre</i>) which is often separated into three branches, extending from 120 to 160 feet in width. When not ramified, its width varies from 20 or 30 to 60 or 70 feet, but is more commonly from 40 to 50 feet. The direction of the vein is north-west and south-east; its underlie is south, and about five or six feet per fathom.	There are five veins worked in this mine. The principal vein (<i>Tschach</i>) is from one foot six inches to three feet in width, the others are from six to twelve inches wide. The direction of this vein is nearly north and south, its underlie is west, and about three feet per fathom. Some of the other veins intersect it.
Ores	Chiefly copper ore, occasionally native copper, blue and green carbonate of copper. Tin, or oxide of tin, also occurs, but not in very great abundance.	Chiefly red silver, native silver, sulphuret of silver, and argentiferous pyrites.	Sulphuret of silver, native silver, prismatic black silver, red silver, native gold, argentiferous galena.	Argentiferous sulphuret of lead, native silver, sulphuret of silver, red silver.
Produce of the ores	24 per cent of fine copper; average produce in 100 parts of ore.	24 oz. per quinta*	Four ounces of silver per quintal of 100 lbs., equivalent to 2½ parts of metal in 1,000 of ore, or 4 per cent.	Six to seven ounces of silver per quintal of 100 lbs. Equivalent to from 2½ to 4½ parts of metal in 1,000 of ore, or from 2-3½ to nearly 4 per cent.
Veinstone	Chiefly quartz, of which many varieties occur.	Chiefly quartz, occasionally amethyst, carbonate of lime, and sulphate of barytes.	Quartz, amethyst, carbonate of lime, pearlapar, and hornstone.	Quartz, pearlapar, and calcareous spar.
Mineral substances accompanying the ore	The ores are generally accompanied by arsenic, in the backs of the lodes, by blende, and by iron, and arsenical pyrites in depth.	The ores are generally accompanied by blende, sulphuret of antimony, and iron pyrites.	The ores are accompanied by blende, sphatose iron, copper and iron pyrites.	The ores are accompanied by blende, sphatose iron, and a little iron and arsenical pyrites.
Depth of the principal shafts	Wood's engine-shaft, 246 fathoms; Pearce's engine-shaft, 275 fathoms. Some of the other engine shafts are scarcely inferior in depth.	Tiro General, 192 fathoms; Gallega shaft, 128 fathoms.	Tiro General, 310 fathoms.	Frankenbachschacht, 180 fathoms.

* Gossan, or Gozzan: oxide of iron and quartz.

COMPARATIVE TABLE of celebrated MINES in EUROPE and AMERICA.

By F. Burr, Esq.—Continued.

	CONSOLIDATED AND UNITED MINES. (At present the richest mines in Cornwall.)	VETA GRANDE MINES. (At present the richest mines in Mexico.)	MINE OF VALENCIANA. (Richest of the Mexican mines at the beginning of the present century.)	MINE OF HIMMELSFURST. (Richest of the Saxon mines at the beginning of the present century.)
Depth of adit at the principal shafts	At Woolf's engine-shaft, 13 fathoms. The average depth of the adit at the other engine-shafts is about 30 or 40 fathoms.	There is no adit to this mine.	There is no adit to this mine.	The adit at the shaft called <i>Frankschacht</i> , is 47 fathoms in depth.
Quantity of water	Varies from 2,000 to 2,000 gallons per minute.	About 80 gallons per minute.	The Valenciana was a dry mine from its commencement in 1760 to 1780, when it first became troubled with water, in consequence of some of the workings being inadvertently communicated with the adjoining mine of Tepeyac; which, although upon the same vein, was extremely wet. The quantity of water raised during the late working appears to have been about 110 gallons per minute, but the regular influx was much less.	80 gallons per minute.
Height to which the water is raised	About 230 fathoms at the consolidated mines, at the united mines, about 118 fathoms.	On an average about 150 fathoms.	210 fathoms.	123 fathoms.
Power employed in drainage	9 steam-engines; 2 of 90-inch cylinder, 2 of 84, 1 of 80, and 2 of 65. A water wheel, 48 feet in diameter.	Usually 10 malacates.*	A steam-engine of 30 inch-cylinder, and 7 malacates.	Two water-wheels, each 48 feet in diameter.
Probable equivalent in actual horse-power	1,500 constantly at work, or a total number of above 4,500.	52 horses constantly working, or a total number of about 100 horses.	65 horses constantly at work, or a total number of about 200.	16 horses constantly at work, or a total number of about 50.
Average annual expense in drainage	12,700 <i>l.</i> taking the average of the last ten years.	20,000 <i>l.</i> per annum.	About 40,000 <i>l.</i> per annum.	Cannot be ascertained, but evidently very small.
Quantity of ore annually produced	16,420 tons of copper ore, a few tons of tin ore.	21,380 tons of silver ore.	22,590 tons of silver ore.	630 tons of silver ore.
Produce to metal	1,517 tons of fine copper, a little tin.	153,000 lbs. troy of silver.	225,390 lbs. troy silver.	6,160 lbs. troy of silver.
Total returns, or value of the above	115,500 <i>l.</i>	423,600 <i>l.</i> per annum.	About 600,000 <i>l.</i>	About 18,000 <i>l.</i>
Total costs of the mine	53,500 <i>l.</i> exclusive of lord's dues, 58,500 <i>l.</i> including lord's dues.	233,170 <i>l.</i> per annum.	197,900 <i>l.</i> per annum.	9,800 <i>l.</i> per annum.
Clear profit to the proprietors	21,000 <i>l.</i> per annum.	171,240 <i>l.</i> per annum	118,750 <i>l.</i> per annum.	3,500 <i>l.</i> per annum.
Amount of capital invested	75,000 <i>l.</i>	130,000 <i>l.</i>	Cannot be ascertained, but known to have been very small.	Cannot be ascertained, but probably very small.
Interest on capital invested	200 per cent. after paying back the original capital.	Nearly 700 per cent. after paying back the original capital.	Not known, but certainly many hundred per cent.	Not known, but probably very high.
Proportion of costs to returns	Costs exclusive of lord's dues, 78 per cent.	About 50 <i>l.</i> per cent.	Costs 60 per cent. In the nine years following, the proportion was 80 per cent., at the end of that time the working of the mine was stopped by the revolution, in the year 1820.	Costs 73 per cent.
Number of men employed	About 2,500 persons, of whom about 1,450 are employed under ground.	About 900, of whom nearly 600 are employed under ground.	3,100 Indians and Mestizoes, of whom 1800 are employed under ground.	700 miners, of whom 550 are employed under ground.
Wages of the miners per day	Probably about 3 shillings on an average.	About 8 or 9 shillings per day.	From 4 to 5 shillings.	About 1 <i>l.</i> 6 <i>s.</i> per day.
Quantity and expense of powder	- - - - -	- - - - -	1,420 cwt.; value 15,330 <i>l.</i>	240 cwt.; value 1,070 <i>l.</i>
Manner in which the ore is disposed of	Sold to the smelting companies, and smelted by them at Swansea, in South Wales.	Chiefly reduced by the company at the hacienda of Sanceda, by smelting and amalgamation.	Sold to the <i>Recoadadores</i> , and reduced by smelting and amalgamation at hacienda, in the neighbourhood of Guanajuato.	Delivered to Government, reduction works in the neighbourhood of Freyberg, where they are partly smelted, and partly amalgamated.

VENTILATION OF MINES.

When men penetrate by narrow passages into the interior of the earth, their respiration, joined to the combustion of candle and gunpowder, are not long of vitiating the air. The decomposition of wood contributes to the same effect, as also the mineral bed itself, especially in coal mines, by the carburetted hydrogen and carbonic acid evolved, and from the absorption of oxygen by pyrites. In many cases, arsenical and mercurial vapours are disengaged. Hence the necessity of maintaining in sub-

* Malacate: a horse whim

terranean cavities a continual circulation of air, which may renew the atmosphere round the miners. The whole of the means employed to produce this effect, constitutes what is called the *ventilation of mines*.

These means are divided into *natural* and *artificial*. The *natural means* are the currents produced by the difference of density between the air of mines and the external air; the *artificial* are air-exhausters or condensers, fires, &c.

The temperature of the air of the subterranean workings surpasses the mean temperature of the place in which the mine is opened. Hence it is lighter in winter, but in summer often heavier than the air of the atmosphere. For this reason, when the mine presents two openings at different levels, the air naturally flows out by the most elevated in winter, and by the lowest in summer. We may take advantage of this circumstance, to lead the air into the bottom of even a very long gallery, opening into the side of the mountain, by piercing a shaft into its roof at some distance from the entrance, and dividing the gallery by a horizontal floor into two parts, which have no mutual communication, except at the furthest extremity—the upper part communicating with the shaft, and the under with the mouth of the gallery. If the two compartments have different dimensions, the air in the smaller sooner comes into an equilibrium of temperature with the rock; and the difference of temperature of the two compartments is sufficient to produce a current. If a streamlet of water flows through this gallery, it facilitates the flow of the air along the lower compartment. If a mine has several openings situated on the same level, it rarely happens but some peculiar circumstance destroys, during the colds of winter and the heats of summer, the equilibrium of the air. But in spring and autumn, when the external air is nearly of the same temperature with that of the mines, the above-named causes are almost always too feeble to excite an issuing current. This effect is, however, frequently obtained by raising over one of the shafts a chimney 20 or 30 yards high, which alone produces the effect of an opening at a different level. It has been remarked that stormy weather usually deranges every system of ventilation. See PITCOAL and VENTILATION.

MINES, BLASTING. It has been often noticed that since the application of gunpowder for blasting, few if any improvements have been made in the methods adopted for cutting through hard rocks; and the great expense of maintaining engine power for pumping and winding during the long period required to sink shafts through such rocks has been, and still is the sole cause of some of the best and richest tracts of minerals in Great Britain lying idle and unproductive, and has been the principal cause of the loss of life so serious and often occurring from explosion in mines.

The improvements, or rather the new system now introduced, will be better understood after a review of the methods and tools heretofore used.

The oldest method of pumping, or taking up the water from the bottom of the shaft during sinking was the Hogar pipe; this was about 4 feet in length, made of leather, and stiffened by rings of metal: the constant damage this was liable to in blasting caused it to be almost abandoned, and in its place the stock and slide pipe was introduced. This consists of two cast-iron pipes sliding into each other as a telescope and kept tight in the joint by a stuffing-box; this contrivance is not only expensive in first cost, but liable to breakage and heavy to handle. Both these modes of pumping are subject to a still greater defect; the pump can only be made nearly under the pump trees, so that during a long time of the sinking it often occurs that only two or three men can be effectually employed in the shaft; this in some of the large shafts (say on a common size used in South Wales, 18 feet by 10 feet) causes serious delay in the progress of the work.

In boring it has been customary to use a borer, the body of which was made of wrought iron, and the bit or end of the borer of shear steel welded on the iron. No attempts appear ever to have been made to fix any definite proportion between the size of the stock or handle and the breadth of the bit; and from this cause a very great portion of the power of the striker has been uselessly expended.

The use of cast steel borers is, in some respects, entirely new as applied to mining, and by the superior hardness of cast steel as compared with shear steel, greatly expedites the process of boring and saves expense; they have also an advantage in transmitting the force of the hammer to the bit, on account of their stiffness or rigidity; and further to prevent loss of power, it is of importance that the bit should be so proportioned to the handle or stock as to work freely in the bore-hole, and at the same time spring or bend as little as possible under the blow of the hammer. The following proportions appear to answer these conditions. (See top of next page.)

The suction pipe now used by the exhibitor, about 20 feet in length, is made of gutta percha, and supersedes the use of the leather Hogar, and the stock and slide; it is not liable to accident, and can be repaired easily; it enables the pump slide to be made in any part of the shaft, and a greater number of men to work it in the shaft at one time.

The introduction of electricity as the power for blasting in connection with the improvements before explained, may be said to constitute a new era in the history of mining.

The apparatus at present used for blasting is Grove's battery of 6 inches square: this is placed in some convenient position near the top of the shaft; two copper wires, coated with gutta serena, are carried down the shafts, and these are connected with the other wires inserted in a small cartridge which is placed in the charge of powder for blasting.

MINES. The miner, in sinking into the earth, soon opens up numerous springs, whose waters, percolating into the excavations which he digs, constitutes one of the greatest obstacles that nature opposes to his toils. When his workings are above the level of some valley and at no great distance, it is possible to get rid of the waters by leading them along a *trench* or a *gallery of efflux*. This forms always the surest means of drainage; and notwithstanding the great outlay which it involves, it is often the most economical. The great advantages accruing from these galleries, lead to their being always established, and without risk, in mines which promise a long continuance. There are many galleries several leagues in length; and sometimes they are so contrived as to discharge the waters of several mines, as may be seen in the environs of Freyberg. Merely such a slope should be given them as is barely sufficient to make the water run, at the utmost from $\frac{1}{300}$ to $\frac{1}{400}$, so as to drain the mine at the lowest possible level.

Whenever the workings are driven below the natural means of drainage, or below the level of the plain, recourse must be had to mechanical aids. In the first place, the quantity of percolating water is diminished as much as possible by planking, walling, or calking up with the greatest possible care those pits and excavations which traverse the water levels; and the lower workings are so arranged that all the waters may unite into wells placed at the bottom of the shafts or inclined galleries; whence they may be pumped up to the day, or to the level of the *gallery of efflux*. In most mines, simple sucking pumps are employed, because they are less subject to give way, and more easy of repair; and as many of these are placed over each other, as the shaft is ten yards deep, below the point where the waters have a natural run.

These draining machines are set in motion by that mechanical power which happens to be the least costly in the place where they are established. In almost the whole of England, and over most of the coal-mines of France and Silesia, the work is done by steam-engines; in the principal metallic mines of France, and in almost the whole of Germany and Hungary, by hydraulic machines; and in other places, by machines moved by horses, oxen, or even by men. If it be requisite to lift the waters merely to the level of a *gallery of efflux*, advantage may be derived from the waters of the upper parts of the mine, or even from waters turned in from the surface, in establishing in the mine of the gallery-level, water-pressure machines, or overshot water-wheels, for pumping up the lower water. This method is employed with success in several mines of Hungary, Bohemia, Germany, Derbyshire, Cornwall, in those of Poullaouen in Brittany, &c. It has been remarked, however, that the copious springs are found rather toward the surface of the soil than in the greatest depths.

TRANSPORT OF ORES TO THE SURFACE.

The ore being extracted from its bed, and having undergone, when requisite, a first sorting, it becomes necessary to bring it to the day, an operation performed in different ways according to circumstances and localities, but too often according to a blind routine. There are mines at the present day, where the interior transport of ores is executed on the backs of men; a practice the most disadvantageous possible, but which is gradually wearing out. The carriage along galleries is usually effected by means of hurdles, barrows, or, still better, by little wagons. These consist of frames resting on four wheels; two larger, which are placed a little behind the centre of gravity, and two smaller, placed before it. When this carriage is at rest, it bears on its four wheels, and leans forward. But when the miner, in pushing it before him, rests on its posterior border, he makes it horizontal; in which case it rolls only upon the two larger wheels. Thus, the friction due to four wheels is avoided, and the roller or driver bears no part of the burden, as he would do with ordinary wheelbarrows. To ease the draught still more, two parallel rails of wood or iron are laid along the floor of the gallery, to which

the wheels of the carriage are adjusted. It is especially in metallic mines, where the ore is heavy, and the galleries straight, that these peculiar wagons are employed. In coal mines, carriages formed with a much larger basket, borne on a railroad by four equal wheels, are preferred. Sometimes the above wain, called on the Continent a *dog* (*chien*), is merely a simple frame on four wheels, on which a basket is set. In the great mines, such as many of the coal and salt mines of Great Britain, the salt mines of Galicia, the copper mines of Fahlun, the lead mines of Alston-Moor, horses and asses are introduced into the workings to drag heavier wagons, or rather a train of wagons attached to one another. These animals often live many years under ground, without ever revisiting the light of day. In other mines, such as those of Worsley, in Lancashire, subterranean canals are cut, upon which the ore is transported in boats.

When the workings of a mine are beginning, when they are still of little depth, and employ few hands, it is sufficient to place over the shaft a simple wheel and axle, by means of which a few men may raise the water-pails, and the baskets or tubs filled with ore; but this method becomes soon inadequate, and should be replaced by more powerful machines.

ACCESSORY DETAILS.

Few mines can be penetrated entirely by means of galleries. More usually where are shafts for mounting and descending. In the pits of many mines, the workmen go down and come up by means of the machines which serve to elevate the ores. In several mines of Mexico, and the north of Europe, pieces of wood, fixed on each side of the pit, form the rude steps of a ladder by which the workmen pass up and down. In other mines, steps are cut in the rock or the ore; as in the quicksilver mines of Idria and the Palatinate, in the salt mines of Wieliczka, and in some of the silver mines of Mexico. In the last they serve for the transport of the ore, which is carried up on men's backs. Lastly, certain mines are entered by means of slopes, some of which have an inclination of more than 30°. The workmen slide down these on a kind of sledge, whose velocity of descent they regulate by a cord firmly fixed at the upper end.

Miners derive light from candles or lamps. They carry the candles in a lump of soft clay, or in a kind of socket terminated by an iron point, which serves to fix it to the rock, or to the timbering. The lamps are made of iron, hermetically closed, and suspended, so that they can not droop, or invert and spill the oil. They are usually hung on the thumb by a hook. Miners also employ small lanterns, suspended to their girdles. Many precautions and much experience are requisite to enable them to carry these lights in a current of air, or in a vitiated atmosphere. It is especially in coal mines liable to the disengagement of carburetted hydrogen, that measures of safety are indispensable against the explosions. The appearance of any halo round the flame should be carefully watched as indicating danger; and the lights should be carried near the bottom of the gallery. The great protector against these deplorable accidents, is the safety lamp. See LAMP OF DAVY.

We can not conclude this general outline of the working of mines, without giving some account of the miners. Most men have a horror at the idea of burying themselves, even for a short period, in these gloomy recesses of the earth. Hence mining operations were at first so much dreaded, that, among the ancients, they were assigned to slaves as the punishment of their crimes. This dislike has diminished with the improvements made in mining; and finally, a profitable and respected species of labor has given mining its proper rank among the other departments of industry. The *esprit de corps*, so conspicuous among seamen, has also arisen among miners, and has given dignity to their body. Like every society of men engaged in perilous enterprises, and cherishing the hopes of great success, miners get attached to their profession, talk of it with pride, and eventually in their old age regard other occupations with contempt. They form, in certain countries, such as Germany and Sweden, a body legally constituted, which enjoys considerable privileges. Miners work usually 6 or 8 hours at a time. This period is called a *journey* (*poste*, in French).

Miners wear, in general, a peculiar dress, the purpose of which is to protect them, as much as possible, from the annoyances caused by water, mud, and sharp stones, which occur in the places where they work. One of the most essential parts of the dress of a German miner is an apron of leather fitted on behind, so as to protect them in sitting on moisture or angular rubbish. In England, the miners wear nothing but flannels; though they frequently strip off all their clothes except their trowsers. In many countries the mallet and the pick, or *pointetrolle* (called in German, *Schegel* and *Eisen*), disposed in a Saint Andrew's cross, are the badge of miners, and are engraved on their buttons, and on everything belonging to mines.

Several of the enterprises executed in mines, or in subserviency to them, merit a distinguished rank among the history of human labors. Several mines are worked to a depth of more than 600 yards, some even to a thousand yards below the surface of the

soil. A great many descend beneath the level of the ocean; and a few even extend under its billows, and are separated from them by a thin partition of rock, which allows their noise, and the rolling of the pebbles, to be heard.

In 1792, there was opened, at Valenciana, in Mexico, an octagonal pit, fully $7\frac{1}{2}$ yards wide, destined to have a depth of 560 yards, to occupy 23 years in digging, and to cost 240,000*l*.

The great drainage gallery of the mines of Clausthal, in the Hartz, is 11,377 yards, or six and a half miles long, and passes upward of 300 yards below the church of Clausthal. Its excavation lasted from the year 1777 till 1800, and cost about 66,000*l*. Several other galleries of efflux might also be adduced, as remarkable for their great length and expense of formation.

The coal and iron mines subservient to the iron works of Mr. Crawshay, at Merthyr-Tydvil, in Wales, have given birth to the establishment, interiorly and above ground, of iron railways, whose total length, many years ago, was upward of 100 English miles.

The carriage of the coal extracted from the mines in the neighborhood of Newcastle to their points of embarkation, is executed almost entirely, both under ground and on the surface, on iron railways, possessing an extent of upward of 500 miles.

There is no species of labor which calls for so great a development of power as that of mines; and accordingly, it may be doubted if man has ever constructed machines so powerful as those which are now employed for the working of some mineral excavations. The waters of several mines of Cornwall are pumped out by means of steam-engines, whose force is equivalent in some instances to the simultaneous action of many hundred horses.

MINES, GENERAL SUMMARY OF.

Mines may be divided into three great classes: 1. Mines in the geological formations anterior to the coal strata; 2. Mines in the secondary formations; 3. Mines in alluvial districts.

The first are opened, for the most part, upon veins, masses, and metalliferous beds.

The second, on strata of combustibles, as coal; and metalliferous or saliferous beds.

The last, on deposits of metallic ores, disseminated in clays, sands, and other alluvial matters, usually superior to the chalk; and even of far more recent formation.

The mines of these three classes, placed, for the most part in very different physical localities, differ no less relatively to the mode of working them, and their mechanical treatment, than in a geological point of view.

MINES OF FORMATIONS ANTERIOR TO THE COAL.

These mines are situated in a few mountainous regions, and their whole amount forms but a small portion of the surface of the earth. The most remarkable of these are—the Cordilleras of South America; the mountains of Hungary; the Altayan mountains; the Ural mountains; the Vosges and the Black Forest; the Hartz, and the east of Germany; the centre of France; the north of Portugal, and the adjacent portions of Spain; Brittany; the corresponding coasts of Great Britain and Ireland; the north of Europe; the Allegany chain; the south of Spain; the Pyrenees; the Alps; the schistose districts on the banks of the Rhine and the Ardennes; the calcareous mountains of England and of Daouria.

MINES OF THE CORDILLERAS OF SOUTH AMERICA.

Few regions are so celebrated for their mineral wealth as the great chain which, under the name of the Cordillera of the Andes, skirts the shores of the Pacific ocean, from the land of the Patagonians to near the northwest point of the American continent. Who has not heard of the mines of Mexico and Potosi? The mineral wealth of Peru has passed into a proverb.

The most important mines of the Cordilleras are those of silver; but several of gold, mercury, copper, and lead, have likewise been opened. These mountains are not equally metalliferous in their whole extent. The workings occur associated in a small number of districts far distant from each other.

In the Andes of Chili, particularly in the province of Coquimbo, some silver mines are explored, which afford chiefly ores of an earthy or ferruginous nature, mingled with imperceptible portions of ores with a silver base, known there under the name of Pacos. The same province also presents copper mines of considerable importance, from which are extracted native copper, orange oxide of copper, carbonate of copper (malachite), and copper pyrites, associated with some muriate of copper. In a few mines, masses of native copper of extraordinary magnitude have been found.

The second metalliferous region of the Andes occurs between the 21st and 15th degrees of south latitude. It includes the celebrated mountain of Potosi, situated in

nearly the 20th degree of south latitude, on the eastern slope of the chain, and several other districts, likewise very rich, which extend principally toward the northwest, as far as the two banks of the lake Titicaca, and even beyond it, through a total length of nearly 150 leagues. All these districts, which formerly depended on Peru, were united in 1778 to the government of Buenos Ayres. The mines of Potosi were discovered in 1545, and have furnished since that period till our days, a body of silver which M. Humboldt values at 230,000,000*l.* sterling. The first years were the most productive. At that time ores were often found which afforded from 40 to 45 per cent. of silver. Since the beginning of the eighteenth century, the average richness of the ore does not exceed above from 3 to 4 parts in 10,000. These ores are therefore very poor at the present day; they have diminished in richness in proportion as the excavations have become deeper. But the total product of the mines has not diminished in the same proportion: abundance of ore having made up for its poverty. Hence, if the mountain of Potosi is not, as formerly, the richest deposit of ore in the world, it may, however, be still placed immediately after the famous vein of Guanaxuato. The ore lies in veins in a primitive clay state, which composes the principal mass of the mountain, and is covered by a bed of clay porphyry. This rock crowns the summit, giving it the form of a basaltic hill. The veins are very numerous; several, near their outcrop, were almost wholly composed of sulphuret of silver, antimoniated sulphuret of silver, and native silver. Others, which offered near the surface merely sulphuret of tin, became richer as they descended. In 1790, seven copper mines were known in the viceroyalty of Buenos Ayres, seven of lead, and two of tin; the last being merely washings of sands found near the river Oraro.

On the opposite flank of the chain, in a low, desert plain, entirely destitute of water, which adjoins the harbor of Iquiqua, and forms a part of Peru, occur the silver mines of Huantajaya, celebrated for the immense masses of native silver which have been sometimes found in them. In 1758, one was discovered weighing eight cwt.

M. Humboldt quotes 40 cantons of Peru as being at the present day most famous for their subterranean explorations of silver and gold. Those of gold are found in the provinces of Huailas and Pataz; the silver is chiefly furnished by the districts of Huantajaya, Pasca, and Chota, which far surpass the others in the abundance of their ores.

The silver mines of the district of Pasco are situated about 30 or 40 leagues north of Lima, in $10\frac{1}{2}$ degrees of south latitude, 4,400 yards above the sea-level, on the eastern slope of the Cordilleras, and near the sources of the river Amazon. They were discovered in 1630. These mines, and especially those of Cero de Yauricocha, are actually the richest in all Peru. The ore is an earthy mass of a red color, containing much iron, mingled with particles of native silver, horn silver, &c., constituting what they call *Pacos*. At first, nothing but these *pacos* was collected; and much gray copper and antimoniated sulphuret of silver were thrown among the rubbish. The mean product of all the ores is $\frac{1}{1250}$; or an ounce and $\frac{28}{100}$ per cwt.; although some occur which yield 30 or 40 per cent. These rich deposits do not seem to be extended to a great depth; they have not been pursued further than 130 yards, and in the greater part of the workings only to from 35 to 45. Forty years ago, these mines, which produced nearly 2,000,000 of piastres annually, were the worst worked in all South America. The soil seemed as if riddled with an immense number of pits, placed without any order. The drainage of the waters was effected by the manual labor of men, and was extremely expensive. In 1816, some Europeans, among whom were several miners from Cornwall, mounted several high-pressure steam-engines, imported from England, which introduced a considerable improvement in the workings.

The mines of the province of Chota are situated in about seven degrees of south latitude. The principal ones are those of Gualeayoc, near Mecucampa, discovered in 1771; their outcrop occurs at the height of 4,500 yards above the sea; the city of Mecucampa itself has 4,000 yards of elevation, that is, higher than the highest summits of the Pyrenees. The climate is hence very cold and uncomfortable. The ore is a mixture of sulphuret of silver and antimoniated sulphuret, with native silver. It constitutes veins, of which the upper portion is formed of *pacos*, and they sometimes traverse a limestone and sometimes a hornstone, which occurs in subordinate beds. The annual produce of the mines is 67,000 marcs of silver, according to Humboldt.

In the districts of Huailas and Pataz, which are at a little distance from the former two, gold mines are worked. This metal is extracted chiefly from the veins of quartz, which run across the primitive schistose mountains. The district of Huailas contains, besides, lead mines. Peru possesses, moreover, some mines of copper.

The quicksilver mines of Huanavelica, the only important mine of this species which has been worked in the New World, occurs on the eastern flank of the Andes of Peru, in 13 degrees of south latitude, at upward of 6,000 yards above the level of the sea. It does not seem referrible to the same class of deposits with the mines hitherto mentioned.

Indications of mercurial deposits have been observed in several other points of the Andes of Northern Peru, and of the south of New Granada.

Lastly, mines of sal-gem are known to exist in Peru, especially near the silver mines of Huantajaya.

On receding from the district of Chota, the Cordilleras are very indifferently stored with metallic wealth, to the isthmus of Panama, and even far beyond it. The kingdom of New Granada offers but a very small number of silver mines. There are some auriferous veins in the province of Antioquia, and in the mountains of Guamoco. The province of Caracas, the mountains of which may be considered as a ramification of the Cordilleras, presents at Aron a copper mine which furnishes annually from 700 to 800 metric quintals (1,400 to 1,600 cwt.) of this metal. Finally, we may state in passing, that there is a very abundant salt mine at Zipaquira, in the province of Santa Fé, and that between this point and the province of Santa-Fé-de-Bogota, a stratum of coal occurs at the extraordinary height of 2,700 yards.

Although Mexico presents a great variety of localities of ores, almost the only ones worked are those of silver. Nearly the whole of these mines are situated on the back or the flanks of the Cordilleras, especially to the west of the chain, nearly at the height of the great table land which traverses this region of the globe, or a little below its level in the chains which divide it. They lie in general between 2,000 and 3,000 yards above the sea; a very considerable elevation, which is favorable to their prosperity, because in this latitude there exists at that height a mean temperature, mild, salubrious, and most propitious to agriculture. There were at the time of Humboldt's visit, from 4,000 to 5,000 deposits of ore exploited. The workings constituted 3,000 distinct mines, which were distributed round 500 head quarters or *Reales*. These mines are not, however, uniformly spread over the whole extent of the Cordilleras. They may be considered as forming eight groups, which altogether do not include a greater space than 12,000 square leagues; viz., hardly more than the tenth part of the surface of Mexico.

These eight groups are, in proceeding from south to north,

1. The group of *Oaxuaca*, situated in the province of this name at the southern extremity of Mexico properly so called, toward the 17th degree of north latitude. Besides silver mines, it contains the only veins of gold explored in Mexico. These veins traverse gneiss and mica-slate.

2. The group of *Tasco*. The most part of the mines which compose it are situated 20 or 25 leagues to the south west of Mexico, toward the western slope of the great plateau.

3. The group of *Biscania*, about 20 leagues northeast of Mexico. It is of moderate extent, but it comprehends the rich workings of Pachuca, Real del Monte, and Moram. The district of Real del Monte contains only a single principal vein, named *Veta Bezicana* of Real del Monte, in which there are several workings; it is, however, reckoned among the richest of Mexico.

4. The group of *Zimapan*. It is very near the preceding, about 40 leagues northwest of Mexico, toward the eastern slope of the plateau. Besides numerous silver mines, it includes abundant deposits of lead, and some mines of yellow sulphuret of arsenic.

5. The *Central group*, of which the principal point is *Guanaxuato*, a city of 70,000 inhabitants, placed at its southern extremity, and 60 leagues N. N. W. of Mexico. It comprises among others the famous mine districts of *Guanaxuato*, *Catorce*, *Zacatecas*, *Sombrerete*; the richest in Mexico, and which alone furnish more than half of all the silver which this kingdom brings into circulation.

The district of *Guanaxuato* presents only one main vein, called the *Veta Madre*. This vein is enclosed principally in clay-slate, to whose beds it runs parallel, but occasionally it issues out of them to intersect more modern rocks. The vein is composed of quartz, carbonate of lime, fragments of clay slate, &c.; and includes the sulphurets of iron, of lead, and of zinc in great quantities, some native silver, sulphuret of silver, and red silver; its power (thickness of the vein) is from 43 to 48 yards. It is recognised and worked throughout a length of upward of 13,000 yards; and contains 19 exploitations, which produced annually well on to 1,200,000*l.* in silver. One of the explorations, that of *Valenciana*, produces 320,000*l.*; being equal to about one fifteenth of the total product of the 3,000 mines of Mexico. Since 1764, the period of its discovery, its neat annual product has never been less than from two to three millions of francs (80,000*l.* to 20,000*l.*); and its proprietors, at first men of little fortune, became, in ten years, the richest individuals in Mexico, and perhaps in the whole globe.

The workings of this mine are very extensive, and penetrate to a depth of 550 yards. They employ a great many laborers.

The district of *Zacatecas* presents in like manner only a single vein in greywacke; which, however, is the seat of several workings.

The deposits mined at *Catorce* are in limestone; the mine called *Purissima de Catorce* has been explored to about 650 yards in depth; and yielded, in 1796, nearly 20,000*l.* There are also mines of antimony in the district of *Catorce*.

Toward the western part of the group of which we are now speaking, copper mines are worked in the provinces of Valladolid and Guadalajara; the ores being chiefly composed of protoxide of copper (orange copper), sulphuret of copper, and native copper. These mines produce about 2,000 metric quintals of copper annually (440,000 lbs. English). In the same district, ores of tin are collected in the alluvial soils, particularly near Mount Gigante. The concretionary oxide of tin, so rare in Europe, is here the most common variety. This metal occurs also in veins.

The central part of Mexico contains many indications of sulphuret of mercury (cinabar); but in 1804 it was worked only in two places, and to an inconsiderable extent.

6. *The group of new Galicia* is situated in the province of this name, about 100 leagues N. W. from Mexico. It comprises the mines of Balanos, one of the richest districts.

7. *The group of Durango and Sonora*, in the intendancies of the same name. It is very extensive. The mines are situated in part on the table land, and in part on the western slope. Durango is 140 leagues N. N. W. of Mexico.

8. *The group of Chihuahua*. It takes its name from the town of Chihuahua, situated 100 leagues N. of Durango. It is exceedingly extensive, but of little value; and terminates at $29^{\circ} 10'$ of north latitude.

Mexico possesses, besides, several mines which are not included in the eight preceding groups. Thus the new kingdom of Leon, and the province of New Saint-André, present abundant mines of lead. New Mexico contains copper mines, and many others.

Lastly, rock salt is mined in several points of New Spain; and coal seems to occur in New Mexico.

The richness of the different districts of the *silver mines* or *reales* is extremely unequal. Nineteen twentieths of these *reales* do not furnish altogether more than one twelfth of the total product. This inequality is owing to the excessive richness of some deposits. The ores of Mexico are principally veins; beds and masses are rare. The veins traverse chiefly, and perhaps only, primitive and transition rocks, among which certain porphyries are remarked as very rich in deposits of gold and silver. The silver ores are mostly sulphuret of silver, black antimoniated sulphuret of silver, muriate of silver (hornsilver), and gray copper. Many explorations are carried on in certain earthy ores, called *collorados*, similar to the *pacos* of Peru. Lastly, there are ores of other metals, which are worked principally, and sometimes exclusively, for the silver which they contain; such are the argentiferous sulphuret of lead, argentiferous sulphuret of copper, and argentiferous sulphuret of iron.

Ores of very great richness occur in Mexico; but the average is only from 3 to 4 ounces per cwt., or from 18 to 25 in 10,000. There are some, indeed, whose estimate does not exceed $2\frac{1}{2}$ ounces. Almost all the argentiferous veins afford a little gold; the silver of Guanajuato, for example, contains $\frac{1}{800}$. The enormous product of the Mexican mines is to be ascribed rather to the great facility of working them, and the abundance of ores, than to their intrinsic richness.

The art of mining was little advanced in this country at the period of Humboldt's journey; the workings presented a combination of small mines, each of which had only one aperture above, without any lateral communications between the different shafts.

The form of these explorations was too irregular to admit of their being called *workings by steps*. The shafts and the galleries were much too wide. The interior transport of the ores is generally effected on the back of men; rarely by mules. The machines for raising the ore and drawing off the water are in general ill combined; and the horse gigs for setting them in motion ill constructed. The timbering of the shafts is very imperfectly executed; the walled portions alone are well done. There are some galleries of drainage, but they are too few, and ill directed. Latterly, English capitalists and miners have formed companies for working the silver mines of Mexico; which will probably produce in time a happy revolution.

The silver ores of Spanish America are treated partly by fusion, and partly by amalgamation, but more frequently by the latter mode; hence the importation of mercury forms there an object of the highest importance, especially since the quicksilver mine of Huancavelica fell in, and ceased to be worked. This mine is the only one in Spanish America which belongs to the government. For the modern state of these mines, see SILVER.

The following table shows, according to M. de Humboldt, what was the annual product of the silver mines of South America, at the beginning of this century. It is founded in a great measure, upon official documents:—

Mexico	-	-	-	2,196,146	mares, or	537,512	kil.,	worth	£4,778,000
Peru	-	-	-	573,508		140,478			1,250,000
Buenos-Ayres	-	-	-	463,098		110,764			984,600
Chili	-	-	-	25,957		6,827			60,680
Total	-	-	-	3,259,153		795,581			7,073,280

To complete our picture of the mineral wealth of Spanish America, it remains to speak of its principal *gold mines*; but these belong to a geological locality, alluvial sands and gravel, very different from that of our present objects. The most important of these gold sands are washed on the western slope of the Cordilleras; viz., in New Grenada, from the province of Barbacoas, to the isthmus of Panama, to Chili, and even to the shores of the seas of California. There are likewise some on the eastern slope of the Cordilleras, in the high valley of the river Amazons. The washings of New Granada produce also some platina.

The mines, properly so called, and the washings of South America, furnish, altogether, 42,575 mares, or 10,418 kilogrammes (22,920 lbs. Eng.) of gold, worth 1,435,720*l*.

MINES OF HUNGARY.

The metallic mines of this kingdom, including those of Transylvania, and the Bannat of Temeschwar, form four principal groups, which we shall denote by the group of the N.W., group of the N.E., group of the E., and group of the S.E.

The group of the N.W. embraces the districts of Schemnitz, Kremnitz, Kœnigsberg, Neuhöhl, and the environs of Schmœlnitz, Bethler, Rosenau, &c.

Schemnitz, a royal free city of mines, and the principal centre of the mines of Hungary, lies 25 leagues to the north of Buda, 560 yards above the sea, in the midst of a small group of mountains covered with forests. The most part of these mountains, the highest of which reaches an elevation of 1,130 yards above the ocean, are formed of barren trachytes (rough trap rocks); but at their foot below the trachytic formation, a formation is observed, consisting of green-stone porphyries, connected with syenites, passing into granite and gneiss, and including subordinate beds of mica-slate and limestone. It is in this formation that all the mines occur.

It has been long known that the green-stone porphyries of Schemnitz have intimate relations with the metalliferous porphyries of South America. M. Beudant, on comparing them with those brought by M. de Humboldt from Guanaxuato, Real del Monte, &c., has recognised an identity in the minutest details of color, structure, composition, respective situation of the different varieties, and even in the empirical character of effervescence with acids. The metalliferous rocks appear at Schemnitz only in a space of small extent, comprehended partly in a small basin, of which the city occupies the south border. They are traversed by veins which, for the most part, cut across the stratification, but which also are sometimes obviously parallel to it. These veins are in general very powerful; their thickness amounting even to more than 40 yards, but their extent in length seems to be usually inconsiderable. They are numerous and parallel to each other. It appears that they have no side plates of vein-stones (*sallebandes*), but that the metalliferous mass reposes immediately on the cheeks or sections of the rock, which is usually more or less altered, and includes always much pyrites near the point of contact, and even to a distance of several feet. The substances which constitute the body of these veins, are drusy quartz, carious quartz, ferriferous carbonate of lime, and sulphate of barytes, with which occur sulphuret of silver mixed with native silver containing more or less gold, which is rarely in visible scales; sulphuret of silver, argenterous galena, blende, copper and iron pyrites, &c. The sulphuret of silver and the galena are the two most important ores. Sometimes these two substances are insulated, sometimes they are mixed in different manners so as to furnish ores of every degree of richness, from such as yield 60 per cent. of silver down to the poorest galena. The gold seldom occurs alone; it generally accompanies the silver in a very variable proportion, which most usually approaches to that of 1 to 30.

The ores of Schemnitz are all treated by fusion; the poor galenas at the smelting house of Schemnitz (bleyhütte), and the resulting lead is sent as working lead to the smelting-houses of Kremnitz, Neuhöhl, and Schernowitz, whither all the silver ores prepared in the different spots of the country are transported in order to be smelted.

The mines of Schemnitz, opened 800 years ago, have been worked to a depth of more than 350 yards. The explorations are in general well conducted. Excellent galleries of efflux have been excavated; the waters for impulsion are collected and applied with skill. It may be remarked, however, that these mines begin to decline from the state of prosperity in which they stood several years ago; a circumstance to be ascribed probably to the same pains being no longer bestowed on the instruction of the officers appointed to superintend them. Maria Theresa established in 1760, at Schemnitz, a school of mines. This acquired at its origin, throughout Europe, a great celebrity, which it has not been able to maintain.

Kremnitz lies about five leagues N.N.W. of Schemnitz, in a valley flanked on the right by a range of hills formed of rocks quite analogous to the metalliferous rocks of Schemnitz. In the midst of these rocks, veins are worked nearly similar to those of Schemnitz; but the quartz which forms their principal mass is more abundant, and contains more native gold. Here also are found sulphuret and hydrosulphuret of antimony.

which do not occur at Schemnitz. The metalliferous district is of very moderate extent and is surrounded by the trachytic district which overlies it, forming to the east and west considerable mountains.

The city of Kremnitz is one of the most ancient free royal cities of mines in Hungary. It is said that mines were worked there even in the times of the Romans; but it is the Germans who, since the middle ages, have given a great development to these exploitations. There exists at Kremnitz a mint-office, to which all the gold and silver of the mines of Hungary are carried in order to be parted, and where all the chemical processes, such as the fabrication of acids, &c., are carried on in the large way.

About six leagues N.N.E. from Schemnitz, on the banks of the Gran, lies the little village of *Neusohl*, founded by a colony of Saxon miners. The mountains surrounding it include mines very different from those of which we have been treating. At *Herrengrand*, two leagues from Neusohl, greywacke forms pretty lofty mountains; this rock is covered by transition limestone, and is supported by mica-slate. The lower beds contain bands of copper ores, chiefly copper pyrites. The mica-slate includes likewise masses of ore, apparently constituting veins in it. These ores have been worked since the 13th century. The copper extracted contains in a hundred weight six ounces of silver.

Eighteen or twenty leagues to the east of *Neusohl*, we meet with a country very rich in iron and copper mines, situated chiefly in the neighborhood of Bethler, Schmölnitz, Einsiedel, Rosenau, &c. Talcose and clay slates form the principal body of the mountains here, along with hornblende rocks. The ores occur most usually in strata. Those of iron, or sparry ore, and especially hydrate of iron, compact and in concretions, accompanied with specular iron ore. They give employment to a great many large smelting-houses. The county of Gömör alone contains 22 works; and that of Zips also a great number. The copper mines lie chiefly in the neighborhood of Schmölnitz and Gölitz. The copper extracted contains about six or seven ounces of silver in the hundred weight. Near Zalathna there is a quicksilver mine nearly inactive; and near Rosenau one of antimony.

To conclude our enumeration of the mineral wealth of this country, it remains merely to state that there are *opal* mines in the environs of Czerventza, placed in the trachytic conglomerate.

GROUP OF THE NORTHEAST, OR OF NAGABANYA.

The mines of this group lie in a somewhat considerable chain of mountains, which, proceeding from the frontiers of Buchowina, where it is united to the Carpathians, finally disappears amid the saliferous sandstones between the *Theiss*, *Lapos*, and *Nagy Szamos*, on the northern frontiers of Transylvania. These mountains are partly composed of rocks analogous to those of Schemnitz, traversed by veins which have much resemblance to the veins of this celebrated spot. Into these veins a great many mines have been opened, the most important of which are those of Nagabanya, Kapnick, Felsőbanya, Mischbanya, Laposbanya, Olaposbanya, Ohlhalapos. All these mines produce gold. Those of Laposbanya furnish, likewise, argentiferous galena; those of Olaposbanya contain copper and iron; and those of Kapnick copper. Realgar occurs in the mines of Felsőbanya; and orpiment in those of Ohlhalapos. Several of them produce manganese and sulphuret of antimony. Lastly, toward the north, in the county of Marmarosh, lies the important iron mine of *Borscha*, and on the frontiers of Buchowina the lead mine of *Radna*, in which also much zinc ore occurs.

The mines composing the group of the East, or of *Abrudbanya*, occur almost all in the mountains which rise in the western part of Transylvania, between *Lapos* and *Maros*, in the environs of *Abrudbanya*. M. Beudant notices in this region, limestones, sandstones, trachytes, basalts, and sienite porphyries, apparently quite analogous to the greenstone porphyries of Schemnitz. It seems to be principally in the latter rocks that the mines forming the wealth of this country occur; but some of them exist also in the mica-slate, the greywacke, and even in the limestone. The principal mines are at Nagyag, Korosbanya, Vorospatak, Boitza, Csertesch, Fatzbay, Almas, Porkura, Butschum, and Stonischa. There are, in all, 40 exploitations; the whole of which produce auriferous ores smelted at the foundry of Zalathna. These mines contain also copper, antimony, and manganese. They are celebrated for their *tellurium* ore, which was peculiar to them prior to the discovery of this metal a few years back in Norway. The auriferous deposits contained in the greenstone porphyry are often very irregular. The mines of Nagyag are the richest and best worked. The numerous veins occur partly in the sienite porphyry, and partly in the greywacke. The auriferous ore is accompanied with galena, realgar, manganese, iron, and zinc. There are iron mines in great beds near Vayda-Huniad and Gyalár. Some Cobalt mines are also noticed.

The group of the S. E., or of the *Banat of Temeschwar*, occurs in the mountains which block up the valley of the Danube at Orsova, through a narrow gorge of which the river escapes. The principal mines are at Oravitz, Moldawa, Szaska, and Dognaczka.

They produce chiefly argentiferous copper, yielding a marc of silver (nearly $\frac{1}{2}$ pound) in the hundred weight, with occasionally a little gold. Ores of lead, zinc, and iron, are also met with. The mines are famous for their beautiful specimens of blue carbonate of copper, and various other minerals. The mine of Moldawa affords likewise orpiment. These metallic deposits lie in beds and veins; the former occurring particularly between the mica-slate and the limestone, or sometimes between the limestone and the sienite porphyry. Well-defined veins also are known to exist in the sienite and the mica-slate. The Bannat possesses moreover important iron-mines at Dombrawa and Ruchersberg; near Dombrawa sulphuret of mercury is found. Cobalt mines occur likewise in these regions.

The mines constituting the four groups now described are not the sole metallic mines possessed by Hungary. A few others, but generally of little importance, are scattered over different parts of this kingdom. Several have been noticed in the portion of the Carpathians which separates Transylvania from Moldavia and Wallachia. Their principal object is the exploration of some singular deposits of galena.

Besides the mines just noticed, Hungary contains some coal mines, numerous mines of rock salt, and several deposits of golden sands situated chiefly on the banks of the Danube, the Marosch, and the Nera.

The mines of the kingdom of Hungary produce annually, according to M. Heron de Villefosse, 5,218 marcs, or 2,810 pounds English of gold, worth 175,976*l.*; and about 85,000 marcs, or 45,767 pounds of silver, worth 186,132*l.* The mines of Transylvania furnish nearly the half of the whole quantity of gold, and one seventeenth of the silver now stated. The other mines of Europe produce together nearly twice as much silver, but merely a few marcs of gold. Hungary affords besides from 18,000 to 20,000 metric quintals (about 4,000,000 lbs. English) of copper annually, and a great deal of iron.

From these mines proceed likewise from 3,000 to 4,000 metric quintals (660,000 to 880,000 lbs. Eng.) of lead; a quantity not more than is needed by the refining-houses for the ores of silver and gold.

MINES OF THE ALTAYAN MOUNTAINS.

At the western extremity of the chain of the Altayan mountains, which separate Siberia from Chinese Tartary, there exists a number of metalliferous veins, in which several important works have been established since the year 1742. They constitute the locality of the mines of Kolywan; the richest in the precious metals of the three districts of this kind existing in Siberia.

These mines are opened up in the schistose formations which surround to the N. and W. and to the S.W. the western declivity of the high granitic chain, from which they are separated by formations consisting of other primitive rocks. These schists alternate in some points with quartzose rocks, called by M. Renovantz hornstone, and with limestone. They are covered by a limestone, replete with ammonites. The metalliferous region forms a semicircle, of which the first lofty mountains occupy the centre.

The most important exploration of this country is the silver mine of Zméof, or Zmeinogarsk, in German Schlangenberg, situated to the N.W. of the high mountains in 51° 9' 25" N. L. and 79° 49' 50" long. east of Paris. It is opened on a great vein, which contains argentiferous native gold, auriferous native silver, sulphuret of silver, hornsilver, gray copper, sulphuret of copper, green and blue carbonated copper, red oxide of copper, copper pyrites, sulphuret of lead, and great masses of testaceous arsenic slightly argentiferous. There occur likewise sulphuret of zinc, iron pyrites, and sometimes arsenical pyrites. The gangues (vein-stones) of these different ores are sulphate of baryta, carbonate of lime, quartz, but rarely fluat of lime. The principal vein, which is of great power, has been traced through a length of several hundred fathoms, and to a depth of no less than 96 fathoms. In its superior portion, it has an inclination of about 50 degrees; but lower down it becomes nearly vertical. Its roof is always formed of clay-slate. On the floor of the vein, the slate alternates with hornstone. This vein pushes out branches in several directions; it is intersected by barren veins, and presents successive stages of different richness. The first years were the most productive. The German miners employed subsequently by the Russian government have introduced regularity into the workings; and have excavated a gallery of 585 fathoms long.

The most important of the other silver mines of this department are those of Tcheremnofski, 3 leagues S.E. of Zméof; those of Smenofski, 10 leagues S.E.; those of Nicolaiski, 20 leagues to the S.S.W.; and of Philipofski, 90 leagues S.E. of the same place. The last mine lies on the extreme frontier of Chinese Tartary. It is not known whether the southern slope of the Altaic chain within the Chinese territories, contains metalliferous deposits.

The ores extracted from these different mines yield on an average per quintal an

ounce of silver, which contains 3 per cent. of gold. Their annual product was toward 1786, according to M. Patrin, 3,000 marcs, or 1,615 lbs. avoirdupois of gold, worth 101,151l.; and 60,000 marcs, or 31,020 lbs. avoird. or silver, worth 130,520l.

The precious metals are not the sole product of this mineral district. There is an important copper-mine 15 leagues N.W. of Zméof, in a chain of hills formed of granitic rocks, schists, porphyries, and shell-limestone, graduating into the plain. The vein presents copper pyrites, sulphuret of copper, and native copper, disseminated in argillaceous substances, more or less ferruginous, and of different degrees of hardness. This mine, which bears the name of Aleiski-Loktefski, furnished annually at the date of 1782, 1,500 quintals (metric), or 330,000 lbs. avoird. of copper, which was coined into money in the country itself.

At Tchakirskoy, on the banks of the Tscharisch, toward the northern extremity of the metalliferous semicircle, mentioned above, there is a mine of argentiferous copper and lead, opened in a very large but extremely short vein. Besides the lead and copper ores, including a little silver, this mine affords a great quantity of ealamine (carbonate of zinc), which forms occasionally fine stalactites of a white or green color.

The northern flank of the Altai mountains presents few mines. Some veins of copper exist 2,000 leagues east of Zméof, near the spot where the river Janissei issues from the Saianean mountains, which are a prolongation of the Altayan chain.

There is no lead-mine, properly so called, in the Altai mountains. Almost all the lead which is required for the treatment of the silver and gold ores is obtained from the department of Nertchinsk, situated 700 leagues off, on the borders of the river *Amour*.

The first smelting-house erected in this district was in the middle of the metalliferous region at *Kolyvan*, the place from which it takes its name. It has been suppressed on account of the dearth of wood in the neighborhood of the mines. The principal existing foundry is that of Bornaoul on the Ob, 50 leagues north of Zméof.

MINES OF THE URAL MOUNTAINS.

This chain of mountains, which begins on the coasts of the icy sea, and terminates in the 50th degree of latitude amid the steppes of the *Kerguis*, after having formed, through an extent of more than 40 leagues, the natural limit between Europe and Asia, contains very rich and very remarkable deposits of metallic ores, which have given rise to important mines of iron, copper, and gold. These explorations are situated on the two slopes, but chiefly on the one that looks to Asia, from the environs of Ekaterinbourg to about 120 or 130 leagues north of that city. They constitute the department of the mines of Ekaterinbourg, one of the three belonging to Siberia.

The copper-mines are pretty numerous, and lie almost wholly on the oriental slope of the chain. They are opened into veins of a very peculiar nature, and which although very powerful at the surface, do not extend to any considerable depth. These veins are in general filled with argillaceous matters, penetrated with red oxide of copper, and mingled with green and blue carbonated copper, sulphuret of copper, and native copper. The most important workings are those of *Tourinski* and *Goumechefski*.

The first are situated 120 leagues north of Ekaterinbourg, toward the 60th degree of N. latitude, at the eastern base of the Uralian mountains, near the banks of the *Touria*. They amount to three, opened in the same vein, which turns round an angle presented by the chain in this place. The ground is composed of a porphyry with a hornstone basis of clay-slate, and of a white or grayish limestone, which form the roof and floor of the vein. The ore yields from 18 to 20 per cent., and these mines produced annually in 1786, 10,000 metric quintals (2,200,000 lbs. avoird.) of copper.

The mine of Goumechefski lies 12 or 15 leagues S.W. of Ekaterinbourg, near a lake bordered by primitive mountains, which form in this region the axis of the chain of the Urals. This mine is celebrated for the beautiful malachites that occur in it. It has furnished almost all the fine specimens of this substance employed in jewellery. The vein, of which the sides are calcareous, is vertical, and runs north and south. It does not sink deeper than about 50 yards, and is filled with a species of coarse pudding-stone, composed of masses of primitive rocks. The ore yields from 3 to 4 per cent. of copper, and the mine furnished about the year 1786, 4,400,000 lbs. avoird. of this metal *per annum*.

The beds of iron ore occur generally at a certain distance from the axis of the central chain. Those of the western slope lie sometimes in a gray compact limestone, which contains *entrochi* and other petrifications, and whose geological age has not been ascertained, but it appears to be much more modern than the rocks of the central chain. Both the one and the other seem to form large veins, which extend little in depth, or rather fill irregular and shallow cavities. The most common ore is the hydrate of iron (bog ore), hematite, or compact iron ore, sometimes mixed or accompanied with hydrate of manganese, and occasionally with ores of zinc, copper, and lead. Black oxide of iron, possessing magnetic polarity, likewise frequently occurs, particularly in the

mines of the eastern slope, on which, in fact, entire mountains of loadstone repose. All these ores, mixed with a greater or less quantity of clay differently colored, are worked by open quarries, and most usually without using gunpowder, or even iron wedges. They yield rarely less than 50 or 60 per cent., and keep in action numerous smelting-houses situated on the two flanks of the chain; the oldest of them have been established since 1628, but the greater number date only from the middle of the 18th century. The most celebrated mines are those of *Balgodat* and *Keskanar*, situated on the eastern slope from 30 to 50 leagues north of *Ekaterinbourg*. In the foundries of the eastern slope, anchors, cannons, bullets, &c., are fabricated; and in the whole a considerable quantity of bar iron. The products of the works on the western side are directly embarked on the different feeders of the Volga, from which they are at no great distance. Those of the eastern slope are transported during winter on sledges to the same feeder streams, after crossing the least elevated passages of the Urals.

The quantity of materials fabricated by the iron-works of both slopes, amounted annually, toward the year 1790, to more than 11,000,000 lbs. avoird. This country is peculiarly favored by nature for this species of industry; for vast deposits of excellent iron ores occur surrounded by immense forests of firs, pines, and birches; woods, whose charcoal is excellently adapted to the fabrication of iron.

The copper-mines of the Uralian mountains, and the greater part of the iron mines and foundries, form a portion of the properties of some individuals, who may be instanced as among the richest in Europe. The Russian government has neglected no opportunity of promoting these enterprises. It has established at *Tourinsky* a considerable colony, and at *Irbitz* a fair which has become celebrated.

There is only one gold mine in the Ural mountains, that of *Beresof*, situated three leagues N.E. of *Ekaterinbourg*, at the foot of the Urals, on the Asiatic side. It is famous for the chromate of lead, or red lead ore, discovered there in 1776, and worked in the following years, as also for some rare varieties of minerals. The ore of *Beresof* is a cavernous hydrate of iron (bog ore), presenting here and there some small striated cubes of hepatic iron, and occasionally some pyrites. It contains 5 parts of native gold in 100,000. This deposit appears to have a great analogy with the deposits of iron ore of the same region. It constitutes a large vein, running from N. to S., encased in a formation of gneiss, hornblende schists, and serpentine, and which does not appear to dip to any considerable depth. It becomes poor in proportion to its distance from the surface. The exploitation, which is in the open air, has dug down 25 yards; having been carried on since the year 1726. The gold is extracted from the ore by stamping and washing. In 1786, 500 mares were collected; but the preceding years had furnished only 200, because they then worked further from the surface. German miners were called in to direct the operations. On some points of the Ural mountains, and the neighboring countries, deposits of an auriferous clay have been noticed; but they have not hitherto been worked.

Beds of chromate of iron have also been discovered in these mountains.

The beautiful plates of mica, well known in mineral cabinets, and even in commerce, under the name of Muscovy tale, or Russian mica, come from the Urals. There are explorations for them near the lake *Tschebarkoul*, on the eastern flank of this chain. From the same canton there is exported a very white clay, apparently a *kaolin*.

25 leagues north of *Ekaterinbourg*, near the town of *Mourzinsk*, there occur in a graphic granite, numerous veins, containing amethysts, several varieties of beryl, emeralds, topazes, &c.

Table of the Production of the Russian Mines during the years 1830, 1831, 1832, 1833, and 1834; by M. Teploff, one of their officers.

MINES OF THE VOSGES AND THE BLACK FOREST.

These mountains contain several centres of exploration of argentiferous ores of lead and copper, iron ores, and some mines of manganese and anthracite.

At the *Croix-aux-mines*, department of the Vosges, a vein of argentiferous lead has been worked, which next to the veins of Spanish America, is one of the greatest known. It is several fathoms thick, and has been traced and mined through an extent of more than a league. It is partly filled with debris, among which occurs some argentiferous galena. It contains also phosphate of lead, antimoniated sulphuret of silver, &c. It runs from N. to S. nearly parallel to the line of junction of the gneiss, and a porphyroid granite, that passes into sienite and porphyry. In several points it cuts across the gneiss; but it probably occurs also between the two rocks. It has never been worked below the level of the adjoining valley. The mines opened on this vein produced, it is said, at the end of the 16th century, 26,000*l.* per annum; they were still very productive in the middle of the last century, and furnished, in 1756, 2,640,000 *lbs.* avoird. of lead, and 6,000 marcs, or 3,230 pounds avoird. of silver.

The veins explored at *Sainte Marie of the mines*, also traverse the gneiss; but their direction is nearly perpendicular to that of the vein of the *Croix*, from which they are separated by a barren mountain of sienite. They contain besides galena, several ores of copper, cobalt, and arsenic; all more or less argentiferous. There is found also at a little distance from *Saint Mary of the mines* a vein of sulphuret of antimony. The mines of *Sainte Marie*, opened several centuries ago, are among the most ancient in France; and yet they have been worked only down to the level of the adjoining valleys.

There has been opened up in the environs of *Giromagny*, on the southern verge of the Vosges, a great number of veins, containing principally argentiferous ores of lead and copper. They run nearly from N. to S., and traverse porphyries and clay-slates; a system which has some analogy with the metalliferous district of Schemnitz. The workings have been pushed so far as 440 yards below the surface. These mines were in a flourishing state in the 14th and 16th centuries; and became so once more at the beginning of the 17th, when they were undertaken by the house of Mazarin. In 1743 they still produced 100 marcs, fully 52 *lbs.* avoird. of silver in the month.

The mines of *La Croix*, of *Sainte-Marie-aux-mines*, and of *Giromagny*, are now abandoned; but it is hoped that those of the first two localities will be resumed ere long.

In the mountains of the Black Forest, separated from the Vosges by the valley of the Rhine, but composed of the same rocks, there occur at *Badenweiler* and near *Hochberg*, not far from Freyburg, workings of lead in great activity. These form six distinct mines, and annually afford 88,000 *lbs.* avoird. of lead, and 200 marcs of silver. In the *Furstenberg* near *Wolfach*, particularly at *Wittichen*, there are mines of copper, cobalt, and silver. The mines of *Wittichen* produced, some years ago, 1,600 marcs, or near 880 *lbs.* avoird. of silver per annum. They supply a manufactory of smalt, and one of arsenical products. A few other inconsiderable mines of the same kind exist in the grand duchy of Baden, and in the kingdom of Wurtemberg.

Several important iron mines are explored in the Vosges; the principal are those of *Framont*, in the department of the Vosges, whose ores are red oxide of iron and brown hematite, which appear to form veins of great thickness, much ramified, and very irregular, in a district composed of greenstone, limestone, and greywacke. The subterranean workings, opened on these deposits, have been hitherto very irregular. There has been discovered lately in these mines, an extremely rich vein of sulphuret of copper. At *Rothau*, a little to the east of *Framont*, thin veins of red oxide of iron are worked; sometimes magnetic, owing probably to an admixture of protoxide of iron. These veins run through a granite, that passes into sienite. At *Saulnot* near *Belfort*, there are iron mines, analogous to those of *Framont*.

In the neighborhood of *Ihann* and *Massovaux*, near the sources of the *Moselle*, veins are worked of an iron ore, that traverse formations of greywacke, clay-slate, and porphyry. Lastly, in the north of the Vosges, near *Bergzabern*, *Erlenbach*, and *Schenau*, several mines have been opened on very powerful veins of brown hematite and compact bog ore, accompanied with a little calamine, and a great deal of sand and debris. In some points of these veins, the iron ore is replaced by various ores of lead, the most abundant being the phosphate, which are explored at *Erlenbach* and *Katzenthal*. These veins traverse the sandstone of the Vosges, a formation whose geological position is not altogether well known, but which contains iron mines analogous to the preceding at *Langenthal*, at the foot of Mount *Tonnerre*, and in the palatinate. Many analogies seem to approximate to the sandstone of the Vosges, the sandstone of the environs of *Saint Avold* (*Moselle*), which include the mine of brown hematite of *Creutzwald*, and the lead mine of *Bleyberg*, analogous to the lead mine of *Bleyberg*, near *Aix-la-Chapelle*.

At *Cruttnich* and *Tholey*, to the north of the *Satrebruck*, mines of manganese are worked, famous for the good quality of their products. The deposit exploited at *Cruttnich* seems to be enclosed in the sandstone of the *Vosges*, and to constitute a vein in it, analogous to the iron veins mentioned above.

There has been recently opened a manganese mine at *Lavelline*, near *La Croix-aux-mines*, in a district of gneiss with porphyry.

In the *Vosges* and the *Black Forest* there are several deposits of anthracite (stone-coal), of which two are actually worked, the one at *Zunswir*, near *Offenbourg*, in the territory of *Baden*, and the other at *Uvoltz*, near *Cernay*, in the department of the *Upper Rhine*. There are also several deposits of the true coal formation on the flanks of the *Vosges*.

MINES OF THE HARTZ.

The name *Hartz* is given generally to the country of forests, which extends a great many miles round the *Brocken*, a mountain situated about 55 miles W.S.W. of *Magdebourg*, and which rises above all the mountains of North Germany, being at its summit 1226 yards above the level of the sea. The *Hartz* is about 43 miles in length from S.S.E. to N.N.W., 18 miles in breadth, and contains about 450 square miles of surface. It is generally hilly, and covered two thirds over with forests of oaks, beeches, and firs. This rugged and picturesque district corresponds to a portion of the *Silva Hercynia* of *Tacitus*. As agriculture furnishes few resources there, the exploration of mines is almost the only means of subsistence to its inhabitants, who amount to about 50,000. The principal cities, *Andreasberg*, *Clausthal*, *Zellerfeld*, *Altenau*, *Lautenthal*, *Wildemann*, *Grund*, and *Goslar*, bear the title of mine-cities, and enjoy peculiar privileges; the people deriving their subsistence from working in the mines of lead, silver, and copper, over which their houses are built.

The most common rock in the *Hartz* is greywacke. It encloses the principal veins, and is covered by a transition limestone. The granite of which the *Brocken* is formed supports all this system of rocks, forming, as it were, their nucleus. Trap and hornstone rocks appear in certain points.

The veins of lead, silver, and copper, which constitute the principal wealth of the *Hartz*, do not pervade its whole extent. They occur chiefly near the towns of *Andreasberg*, *Clausthal*, *Zellerfeld*, and *Lautenthal*; are generally directed from N.W. to S.E., and dip to the S.W., at an angle of 80° with the horizon.

The richest silver mines are those of the environs of *Andreasberg*, among which may be distinguished the *Samson* and *Newfang* mines, worked to a depth of 560 yards. In the first of them there is the greatest *step* exploitation to be met with in any mine. It is composed of 80 *direct steps*, and is more than 650 yards long. These mines were discovered in 1520, and the city was built in 1521. They produce argentiferous galena, with silver ores properly so called, such as red silver ore, and ore of cobalt.

The district which yields most argentiferous lead is that of *Clausthal*; it comprehends a great many mines, several of which are worked to a depth of 550 yards. Such of the mines as are at the present day most productive, have been explored since the first years of the eighteenth century. The two most remarkable ones are the mines of *Dorothy*, and the mine of *Caroline*, which alone furnish a large proportion of the whole net product. The grant of the *Dorothy* mine extends over a length of 257 yards, in the direction of the vein, and through a breadth of nearly 22 yards perpendicularly to that direction. Out of these bounds, apparently so small, but which however surpass those of the greater part of the *concessions* in the *Hartz*, there was extracted from 1709 to 1807 inclusively, 883,722 mares of silver, 768,845 quintals of lead, and 2,385 quintals of copper. This mine and that of *Caroline* have brought to their shareholders in the same period of time, more than 1,120,000*l.*; and have besides powerfully contributed by loans without interest to carry on the exploration of the less productive mines. It was in order to effect the drainage of the mines of the district of *Clausthal*, and those of the district of *Zellerfeld* adjoining, that the great gallery of efflux was excavated.

Next to the two districts of *Clausthal* and *Zellerfeld*, and *Andreasberg*, comes that of *Goslar*, the most important working in which is the copper mine of *Rammelsberg*, opened since the year 968, on a mass of copper pyrites, disseminated through quartz, and mingled with galena and blende. It is worked by shafts and galleries, with the employment of fire to break down the ore. This mine produces annually from 1,200 to 1,300 metric quintals (about 275,000 lbs. avoird.) of copper. The galena extracted from it yields a small quantity of silver, and a very little gold. The latter metal amounts to only the five-millionth part of the mass explored; and yet means are found to separate it with advantage. The mine of *Lauterberg* is worked solely for the copper, and it furnishes annually near 66,000 lbs. avoird. of that metal.

Besides the explorations just noticed, there are a great many mines of iron in different parts of the *Hartz*, which give activity to important forges, including 21 smelting

cupolas. The principal ores are sparry iron, and red and brown hematites, which occur in veins, beds, and masses. Earthy and alluvial ores are also collected.

The territory of Anhalt-Bernbourg presents, toward the southeast extremity of the Hartz, lead and silver mines, which resemble closely those of the general district. They produce annually 33,000 lbs. avoird. of lead.

At the southern foot of the Hartz, at Ilfeld, there is a mine of manganese.

The exploration of the Hartz mines may be traced back for about 900 years. The epoch of their greatest prosperity was the middle of the eighteenth century. Their gross annual amount was in 1808 upward of one million sterling. Lead is their principal product, of which they furnish annually 6,600,000 lbs. avoird., with 36,000 mares, or 18,700 lbs. avoird. of silver, about 360,000 lbs. avoird. of copper, and a very great quantity of iron. They are celebrated for the excellence of the mining operations; and the activity, patience, and skill, of their workmen.

The Hartz is referred to especially for the manner in which the waters are collected and economized for floating down the timber, and impelling the machinery. With this view, dams or lakes, canals, and aqueducts, have been constructed, remarkable for their good execution. The water-courses are formed either in the open air round the mountain-sides, or through their interior as subterranean galleries. The open channels collect the rain-waters, as well as those proceeding from the melting of snows, from the springs and streamlets, or small rivers that fall in their way. The subterranean conduits are in general the continuation of the preceding, whose circuits they cut short. These water-courses present a development in whole of 125 miles. The banks of some of the reservoirs are of an extraordinary height. In the single district of Clausthal there are 34 tanks, which supply water to 92 wheels of nearly 30 feet diameter; 55 of these serve for the drainage of water, and 37 for the extraction of ores.

MINES OF THE EAST OF GERMANY.

We shall embrace under this head the mines opened in the primitive and transition territories, which constitute the body of a great portion of Bohemia, and the adjacent parts of Saxony, Bavaria, Austria, Moravia, and Silesia.

Among the several chains of small mountains that cross these countries, the richest in deposits of ore is the one known under the name of the *Erzgebirge*, which separate Saxony from Bohemia on the left bank of the Elbe.

The *Erzgebirge* contains a great many mines, whose principal products are *silver, tin, and cobalt*. These mines, whose exploration remounts to the twelfth century, and particularly those situated on the northern slope within the kingdom of Saxony, have been long celebrated. The school of mines established at Freyberg was at one time considered as the first in the world. This is a small city near the most important workings, 8 leagues W.S.W. of Dresden, toward the middle of the northern slope of the *Erzgebirge*, 440 yards above the level of the sea, in an agricultural and trading district, well cleared of wood. These circumstances have modified the working of the mines, and render it difficult to draw an exact parallel between them and those of the Hartz, which are their rivals in good exploration; they are peculiarly remarkable for the perfection with which the engines are executed both for drainage and extraction of ores, all moved by water or horses; for the regularity of almost all the subterranean labors; and for the beauty of their *walling* masonry. In the portion of these mountains belonging to Saxony, the underground workings employ directly from 9,000 to 10,000 men, who labor in more than 400 distinct mines, all associated under the same plan of administration.

The *silver* mines of the *Erzgebirge* are opened on veins which traverse gneiss, and though quite different in this respect from the argentiferous veins of *Guanaxuato*, *Schemnitz*, and *Znoef*, present but a moderate thickness, never exceeding a few feet. They form several groups, whose relative importance has varied very much.

For a long time back, those of the environs of Freyberg are much the most productive; and their prosperity has been always on the advance, notwithstanding the increasing depth of the excavations. The deepest of the whole is that of *Kuhlschacht*, which penetrates to 450 yards beneath the surface, that is, nearly down to the sea-level. The most productive and the most celebrated is the mine of *Himmelsfürst*; that of *Beschert-gluck* is also very rich.

Among the explorations at *Erzgebirge*, there are none which were formerly so flourishing as those of *Marienberg*, a small town situated 7 leagues S.S.W. of Freyberg. In the sixteenth century, ores were frequently found there, even at a short distance from the surface, which yielded 85 per cent. of silver. The disasters of the thirty years' war put a term to their prosperity. Since that period, they have continually languished; and their product now is nearly null.

Our limits do not permit us to describe in detail the silver mines that occur near

Ehrenfriedersdorf, Johanna-Georgenstadt, Annaberg, Oberwiesenthal, and Schneeberg. Those of the last three localities produce also cobalt.

The mines of Saint-Georges, near Schneeberg, opened in the fifteenth century as iron mines, became celebrated some time after as mines of silver. Toward the end of the fifteenth century, a mass of ore was found there which afforded 400 quintals of silver; on that lump, Duke Albert kept table at the bottom of the mine. Their richness in silver has diminished since then; but they have increased more in importance during the last two hundred years, as mines of cobalt, than they had ever been as silver mines. Saxony is the country where cobalt is mined and extracted in the most extensive manner. It is obtained from the same veins with the silver. Smalt, or cobalt-blue, is the principal substance manufactured from it. The lead and the copper are in this country only accessory products of the silver mines, from which 120,000 lbs. avoid. of the first of these metals are extracted, which are hardly sufficient for the metallurgic operations; and from 50,000 to 60,000 lbs. of copper. A little bismuth is extracted from the mines of Schneeberg and Freyberg. Some manganese is found in the silver mines of the Erzgebirge, and particularly at Johanna-Georgenstadt.

The mines of Saxony produce a little argentiferous galena, and argentiferous gray copper; the minerals with a base of native silver are the principal ores; they are treated in a great measure by amalgamation. All those of Freyberg are carried to the excellent smelting-house of Halsbrück, situated on the Malde, near that city. The average richness of the silver ores throughout Saxony is only from 3 to 4 oz. per quintal: viz., nearly equal to that of the ores of Mexico, and very superior to the actual richness of the ores of Potosi. The silver extracted from them contains a little gold. The Saxon mines produce annually 52,000 marcs of silver. Of these, the district of Freyberg alone furnishes 46,000; and among the numerous mines of that district, that of Himmelsfurst of itself produces 10,000 marcs.

Silver mines exist also on the southern declivity of the Erzgebirge, which belongs to Bohemia, at *Joachimsthal* and *Bleystadt*, to the northeast of Eger. Argentiferous galena is chiefly extracted from these. The mines of Joachimsthal have been explored to a depth of 650 yards. They were formerly very flourishing; but in 1805 they were threatened with an impending abandonment. The ancient mines of Kuttenberg, situated in the same region, have been excavated, according to Agricola, to upward of 1,000 yards from the surface soil.

The southern slope of the Erzgebirge possesses cobalt mines like the northern slope; but they are of much less importance. Some occur, particularly in the neighborhood of Joachimsthal. Lastly, on the same slope, slightly-productive copper mines are mentioned at Gröslitz, near Joachimsthal; at Catharineberg, 8 leagues north of Saatz; and at Kupferberg, lying between the two. At Gröslitz, the ore is a cupreous pyrites, accompanied by blende. The ores of Catharineberg are argentiferous.

Next to the silver mines, the most important explorations of the Erzgebirge are those of tin. This metal occurs in veins, massive, and disseminated in masses of hyalin gray quartz, imbedded in the granite; it is also found in alluvial sands. The most important tin mine of the Erzgebirge is that of Altenberg, in Saxony, which has been under working since the fifteenth century. Some tin is mined also near Gayer, Ehrenfriedersdorf, Johanna-Georgenstadt, Scheibenberg, Annaberg, Seiffen, and Marienberg, in Saxony. At Zinnwald it is also found; where the stanniferous district belongs partly to Saxony and partly to Bohemia; as also important mines occur in the latter territory at Schlaackwald and Abertham, and slightly-productive ones at Platten and Joachimsthal. In several of these mines, particularly at Altenberg and Gayer, fire is employed for attacking the ore, because it is extremely hard. In almost the whole of them, chambers of too great dimensions have been excavated, whence have arisen, at different epochs, vexatious sinkings of the ground. One of these may still be seen at Altenberg, which is 130 yards deep, and nearly 50 in breadth. The mines of Abertham are explored to a depth of 550 yards, and those of Altenberg to 330. The tin mines of the Erzgebirge produce annually 484,000 lbs. avoid. of this metal.

The tin ores are accompanied by arsenical pyrites, which, in the roasting that it undergoes, produces a certain quantity of arsenious acid.

The Erzgebirge presents also a great many iron mines, particularly in Saxony, at Rodenberg, near Cradorf, in the county of Henneberg, where the workings penetrate to a depth of 220 yards, and in Bohemia, at Platten, where may be remarked especially the great explorations opened on the vein of the *Irrgang*.

There is also in the Erzgebirge a mine of anthracite (stone coal) at *Schænfeld*, near Frauenstein, in Saxony.

The ancient rock-formations which appear in the remainder of Bohemia, and in the adjacent portions of Bavaria, Austria, Moravia, and Silesia, are much less rich in metals than the Erzgebirge. No explorations of much importance exist there.

The *Fichtelgebirge*, a group of mountains standing at the western extremity of the

Erzgebirge, between Hoff and Bayreuth, contains some mines, among which may be noticed, principally, mines of magnetic black oxide of iron.

Argentiferous lead mines have been mentioned at *Miess*, 25 leagues W.S.W. of Prague, at the N.E. base of the western part of *Bomerwaldgebirge*, a chain of mountains which separate Bohemia from Bavaria. There are some also at *Prasibram*, 12 leagues S.W. of Prague, at the extremity of the mountains which separate Behrun from Moldau. In the latter, the argentiferous galena is accompanied by blende, in which the presence of cadmium has been observed. These mines, and those of Joachimsthal and of Bleystadt, furnish annually at present 220,000 lbs. avoird. of lead, and from 2,000 to 3,000 marcs of silver. The circle of Behrun, to the S.W. of Prague, contains some inconsiderable mines of mercury. The eastern part of the *Bomerwaldgebirge*, which separates Bohemia from Austria and Moravia, presents some mines on its southeast slope. Those of the environs of *Iglau*, in Moravia, and some others situated in Austria, produce annually from 4,000 to 5,000 marcs of silver. The mines of these two countries yield also copper, and in several the copper ores are argentiferous. Moravia comprehends several iron works, which are in part supplied by magnetic iron ores analogous to those of Sweden.

The northeast slope of the *Riesengebirge* (giant mountains), which separate Bohemia from Silesia, presents also several explorations. The argentiferous copper mines of *Rudolstadt*, and of *Kupferberg*, have been stated as producing annually a considerable quantity of copper, and from 600 to 700 marcs of silver; as also the cobalt mine of *Maria-anna Querback*, the whole in the circle of Quær; and the mines of arsenical pyrites at *Reichenstein*, in the circle of Glatz. A mine of chrysoprase exists in the mountain of *Kosennitz*.

MINES OF THE CENTRE OF FRANCE.

The ancient formations, principally granitic, which constitute the ground of several departments of the centre and south of France, are hardly any richer in explorations than the districts mentioned at the end of the Black Forest. Only some insulated mines are to be observed here, of which a very few possess any importance. These all occur toward the eastern border of the mass of primitive formations, in a zone characterized by a great abundance of schistose rocks.

At *Villefort* and at *Viallaze*, in the department of the *Lozère*, and in some places adjoining, several veins of argentiferous galena are worked which traverse the gneiss and the granite. These mines, remarkable at present for the regularity of their workings, employ 300 laborers, and produce annually about 220,000 lbs. avoird. of lead, and 1,600 marcs of silver.

The city of *Vienne*, in *Dauphiny*, is built on a hill of gneiss separated by the Rhone from the main body of the primitive formations, and in which veins of galena occur, which are now imperfectly mined. Other lead mines of less importance are observed at *St. Julien-Molin-Molette*, department of the *Loire*, and at *Jour*, department of the *Rhone*.

At *Chessy*, a village situated 7 leagues northwest of *Lyons*, there occur in a talcose schist very extensive veins of cupreous pyrites, by no means rich, but which have, nevertheless, been worked successfully during the latter part of the eighteenth century, and several years of the present; at that period, there was found in a sandstone which covers the talcose schist, and which appears referrible to the red sandstone or the variegated sandstone, a bed containing a great quantity of blue carbonate of copper and protoxide of copper, to the working of which the miners have since directed their principal attention. There exists at *Saint-Belle*, 2 leagues to the south of *Chessy*, a deposit of copper pyrites like that of *Chessy*, which was at one time worked, but is now standing still. At *Romanèscho*, in the department of *Saone et Loire*, a very abundant deposit of oxide of manganese is observed, apparently forming a mass in the granite, or perhaps above it. The workings are very irregular.

In the mountain of *Ecouphettes*, near *Couches*, in the same department, an ore of oxide of chrome has been occasionally worked.

At *Malbose*, in the department of the *Lozère*, a feeble vein of sulphuret of antimony is mined.

There are also in the centre of France some explorations of galena, antimony, and manganese, which appear to be of too little importance to be noticed in detail.

Some years ago a tin ore was discovered at *Vaubry*, 6 leagues N.N.W. of *Limoges*. At present, researches are making with a view of discovering deposits of such magnitude as to pay the expense of working it.

MINES OF THE NORTH OF PORTUGAL AND THE ADJOINING PARTS OF SPAIN.

The Carthaginians appear to have worked tin mines in this part of the peninsula. It is said that some formerly existed in Portugal in the environs of *Viscu*, a province of *Beirn*, at

a place called *Burraco de Stanno*. Some veins of the same metal were discovered in 1787, near Monte-Rey, in the south of Galicia. They were fully two yards thick, and were incased in granite. This province presents also deposits of sulphuret of antimony. Some analogous ores are found in Castille and Estremadura. Lead ores were worked in the last century not far from Mogadouro, on the banks of the Sabor, in the province of Tras-los-Montes, and near Longroiva on the banks of the Rio-Prisco. Mines of plumbago occur near Mogadouro. There are also some iron mines in the same country near Felgueira and Torredemnacorvo. They supply the iron-works of Chapa-cunha. Two very ancient establishments of the same kind exist in the Estremadura of Portugal; the one in the district of Thomar, and the other in that of Figuero dos Vinhoss: they are supplied by mines of red oxide of iron, situated on the frontiers of this province and of Beira. One deposit of quicksilver ore occurs at Couna in Portugal. At Rio Tinto in Spain, on the frontiers of Portugal, there is a copper mine which produces about 33,000 lbs. avoird. of this metal per annum. The ore is a copper pyrites. The mountains in the environs of Oporto present everywhere indications of the ores of copper and other metals; and it appears that all this part of the peninsula is in general rich in metallic treasures, but that the want of wood prevents their being mined to advantage.

Besides, many of the deposits which originally existed there must be in a great measure exhausted. It was in these countries chiefly that the gold and silver mines lay, which the Carthaginians and Romans worked with so much advantage, and contested in so keen a manner. Near Loria (the ancient Numantium), Azagala, and Burgos, considerable vestiges of the ancient workings may still be seen.

MINES OF BRITANNY.

Britanny has hardly a better share in mineral wealth than the countries we have just passed in review. There exist in it at this moment only two important exploitations; which are, the lead mines of *Poullaouen* and *Huelgoat*, situated near Carhaix. The mine of Huelgoat, celebrated for the plomb-gomme (hydro-aluminate) discovered in it, is opened on a vein of galena, which traverses transition rocks. The workings have subsisted for about three centuries, and have attained to a depth of 220 yards. The vein of Poullaouen, called the New Mine, was discovered in 1741. It was powerful and very rich near the surface; but it became subdivided and impoverished with its depth, notwithstanding which the workings have been sunk to upward of 180 yards below the surface. In these mines there are fine hydraulic machines for the drainage of the waters, with wheels from 14 to 15 yards in diameter; and water-pressure machines have been recently constructed. The mines employ more than 900 workmen, and furnish annually more than 1,200,000 lbs. avoird. of lead, several thousand pounds of copper, and 2,000 marcs, or 1,034 lbs. avoird. of silver. These are the most important metallic mines of France. Several veins of galena exist at *Chatelaudren*, near Saint-Briex, but they are not worked at present. There is also one at Pompean, near Rennes, which has been worked to a depth of 140 yards, but is in like manner now abandoned. It affords, besides the galena, a very large quantity of blende (sulphuret of zinc), of which attempts are making to take advantage. There occurs, also, a lead mine at Pierreville, department of the Channel, in a formation connected with the system of Britanny. It is opened on a vein which traverses a limestone pretty analogous to that of Derbyshire. The same department presents a deposit of sulphuret of mercury at Ménildot. A few years ago, some tin ore was discovered at Pyriac, near Guérande, in the department of the Loire Inférieure, but the researches since made to find workable deposits have been unsuccessful. A mine of antimony was worked at La Ramée, department of La Vendée. Several of the coal deposits lately mined in the departments of La Sarthe, La Mayenne, and Mayenne-et-Loire, ought probably to be regarded as more ancient than the genuine coal measures.

Table of the production of the French mines, during the year 1832.*

Species of Mine.	Number of mines.	Extent of surface conceded.	Number of workmen.	Production is in 10ths of a ton.	Value of the rough product in francs.
<i>Metallic Substances.</i>		<i>Kilom. carrés.</i>			
Antimony -	16	93,8954	130	Melted antim. 1-030,98	71-232,75
Copper - -	8	274,18	258	Black copper 1-376	247.680
Iron - - -	131	1-051,391	8917	Rough ore 15-814,690	3,630-806,81
Manganese -	8	16,54	66	6-087	66-849,88
Gold - - -	1	0-49			
Lead and silver	33	614,23	1259	8-505	742-051
Zinc - - -	1	6,80			

* *Annales des Mines*, tom. v., 1834, p. 676).

MINES OF THE CORRESPONDING COASTS OF GREAT BRITAIN AND IRELAND.

The mines comprehended in this section are situated, 1, in Cornwall and Devonshire, 2, in the S.E. of Ireland; 3, in the island of Anglesey and the adjoining part of Wales; 4, in Cumberland, Westmoreland, and the north of Lancashire, and the Isle of Man; 5, in the south of Scotland; 6, in the middle part of the same country.

Cornwall and Devonshire present three principal mining districts; viz., the portion of Cornwall situated in the environs and S.W. of Truro, the environs of St. Austle, and the environs of Tavistock.

The first of these districts is the most important of the three in the number and richness of its mines of copper, tin, and lead. The ores of copper, which consist almost entirely of copper pyrites and common sulphuret of copper, constitute very regular veins running nearly from east to west, and incased most frequently in a clay-slate of a talcose or hornblende nature, called *killas*, and sometimes in granite, which forms protuberances in the middle of the schists. The tin occurs principally in veins, which, like the preceding, traverse the *killas* and the granite. They are also very often directed nearly from east to west, but they have a different inclination, or dip, from that of the copper veins, which cut them across and interrupt them, and are consequently of more recent formation. The tin ore forms also masses, which appear most usually attached to the veins by one of their points. Lastly, it is found in small veins which traverse the granite, principally near the points where this rock touches the *killas*. Certain veins present the copper and tin ores together; a mixture which occurs chiefly near the points of intersection of the two metallic veins. Certain mines furnish at once both copper and tin; but the most part produce in notable quantity only one of these metals. The most important copper mines are situated near Redruth and Camborn; among which may be noted particularly those called *Consolidated Mines*, *United Mines*, Huel-Alfred, Dolcoath, Poldice, &c. The principal tin mines are situated still farther to the southwest, near Helston, Saint-Yves, &c. Those called Huel Vor, Great Huas, are particularly noticed. There are several mines in Cornwall of which the crossing veins which at once intersect and throw out the veins of copper and tin, contain argentiferous galena and several ores of silver. There existed formerly mines of argentiferous lead near Helston and Truro. There may be now seen near Saint Michael an ore which, melted and cupelled on the spot, yields from an ounce and a half to two ounces of silver per quintal. Near Calstock a silver mine is worked, called *Huel-Saint-Vincent*, which has afforded, it is said, in some months, from 900 to 1,000 lbs. avoird. of that metal. The ore, consisting of hornsilver and native silver, is treated on the spot.

In the environs of Saint Austle, the copper mines of *East Crinnis* and *West Crinnis* deserve to be noticed, as well as the tin mine of Polgooth, opened on a tin vein; and the mine of Carclaise, explored in the open air on a system of small veins of this metal.

Near Tavistock there occur mines of copper, tin, and lead. Among the last may be remarked particularly that called *Huel Betsey*, of which the ores melted and cupelled on the spot, afford an ounce and a half of silver per cwt.; and that of Beeralston, whose ore is sent to Bristol to be smelted there. It yields from four to five ounces of silver per cwt.

There are mines of antimony at *Huel-Boys* in Devonshire, and at Saltash in Cornwall.

The tin and copper ores of Cornwall are accompanied with arsenical pyrites, which is turned to some account by the fabrication of white arsenic (arsenious acid).

Cornwall and Devonshire produce annually about 6,160,000 lbs. avoird. of tin; 18,700,000 lbs. avoird. of copper; and 1,760,000 lbs. avoird. of lead. See COPPER and TIN.

The tin is treated at the mine localities: but the copper ores are sent in their natural state to Swansea in South Wales, to be smelted.

Wood and labor being very dear in Cornwall and Devonshire, the mineral deposits of these counties can not be worked out so completely, nor can the mechanical preparation of the ore be so far pushed, as in several other parts of the world. But all the operations which appear advantageous are conducted in the most judicious, most economical, and most expeditious manner. Steam-engines are erected there, some of them possessing the power of several hundred horses. Many of the mines are explored to a depth of upward of 400 yards; and several are celebrated for the boldness of their workings. The one called *Botallock Mine*, situated in the parish of St. Just, near the Cornwall cape, is opened amid rocks which form the seacoast, and stretches several hundred yards under the sea, and upward of 200 yards beneath its level. In some points so small a thickness of rock has been left to support the weight of the waters, that the rolling of pebbles on the bottom is distinctly heard by miners during a storm. The mine of Huel-werry, near Penzance, was worked by means of a single shaft opened on the coast, in a space left dry by the sea only for a few hours at every ebb. A small wooden tower was built over the mouth of the shaft, which, being carefully calked, kept out

the waters of the ocean when the tide rose, and served to support the machines for raising the ore and drainage. A vessel driven by a storm overturned it during the night, and put a period to this hazardous mode of mining, which has not been resumed.

The most considerable mines of Ireland are those of Cronebane and Tingrony, and of Ballymartagh, situated three leagues S.W. of Wicklow, in the county of the same name. Their object is to work the copper pyrites, accompanied with some other ores of copper, galena, sulphuret of antimony, as well as pyrites of iron, which forms several flattened masses in the clay-slate. Pretty extensive workings have been made here; and the ore was transported in its natural state to Swansea. Veins or masses of copper pyrites and galena are mined in some other points of the southeast of Ireland, but none of them with any notable advantage. The principal is the lead mine situated in the county of Tipperary, near the village called Silver Mines, absurdly enough, because, though silver was sought for in the lead, none was extracted. Many iron mines anciently existed in Ireland, but the destruction of the forests has considerably diminished their number and activity, so that only a few remain in Kilkenny, Wicklow, and Queen's County.

The isle of Anglesey is celebrated for its copper mines, the principal of which are Mona-mine and Parys-mountain. The ore is a copper pyrites, sometimes of considerable volume, lying in masses in a formation containing serpentines and different talcose rocks. For a long time the workings were carried on in the open air, but the exterior exploration has been thereby compromised. The neighboring coasts of Wales present some mines of the same nature. All the ores are treated in a smelting-house established in the isle of Anglesey. The formation of slate-clay and greywacke, which constitutes the greater part of Wales, and some of the adjoining districts of England, includes several lead mines, of which we shall presently speak in noticing those of far greater importance contained in the more recent limestone formations of the same regions.

Pretty important mines of copper pyrites and red hematitic iron are worked in Westmoreland, and in the neighboring parts of Cumberland and Lancashire. The copper ores, and a portion of the iron ones, are embarked for Swansea. The rest of the iron ore is treated on the spot in blast furnaces supplied with wood charcoal. The isle of Man affords indications of lead, copper, and iron, in the mountains of Snafle, which constitute its centre. At Borrowdale in Westmoreland, a mine of graphite (plumbago) has been worked for a long period. It furnishes the black lead of the English pencils, so celebrated over the world. The mineral occurs in mass in a talcose formation.

There are famous lead mines in the south of Scotland, at Leadhills in Lanarkshire; the veins of which are incased in greywacke. Some manganese has also been found. At Cally, in Kirkcudbrightshire, a copper mine has been lately discovered; and a mine of antimony has been known for some time at West Kirk in Dumfriesshire; but neither has been turned to good account.

In the middle part of Scotland, the lead mines of Strontian in Argyllshire deserve to be noticed, opposite to the northeast angle of the isle of Mull. They are opened on veins which traverse gneiss. According to Mr. John Taylor, these mines and those of Leadhills produce annually 5,610,000 lbs. avoird. of lead.

Explorations of manganese were begun at Grantown on the banks of the Don, a river which falls into the German ocean at Aberdeen. A mine of coarse graphite has also been worked at Huntley.

A copper mine was discovered some years back in one of the Shetland isles; and chromate of iron is now extensively worked there in serpentine and tale.

MINES OF THE NORTH OF EUROPE.

These mines are situated for the most part in the south of Norway, toward the middle of Sweden, and in the south of Finland, a little way from the shortest line drawn from the lake Onega to the southwest angle of Norway. A few mines occur in the northern districts of Norway and Sweden. The main products of these several mines are iron, copper, and silver.

The iron mines of Norway lie on the coasts of the gulf of Christiania, and on the side facing Jutland, principally at Arendal, at Krageroe, and the neighborhood. The ores consist almost solely of black oxide of iron, which forms beds or veins of from 4 to 60 feet thick, incased in gneiss, which is accompanied with pyroxene (augite), epidotes, garnets, &c. These iron ores are reduced in a great many smelting forges, situated on the same coasts, and particularly in the county of Laurvig. Their annual product is about 16½ millions of pounds avoird. of iron, in the form of cast iron, bar iron, sheet iron, nails, &c.; of which one half is exported.

Norway possesses rich copper mines, some of which lie toward the south and the centre of the country, but the most considerable occur in the north, at *Quikkene*, *Laken*, *Seloe*, and *Rævaas*, near Dronheim. The mine of *Rævaas*, 16 miles from Dronheim to

the S.E. of this city, is opened on a very considerable mass of copper pyrites, and has been worked in the open air since 1664. It has poured into the market from that time, till 1791, 77 millions of pounds avoird. of copper. In 1805, its annual production was 864,600 lbs.; while all the other mines of Norway together do not furnish quite one fourth of that amount.

Norway comprehends also some celebrated silver mines. They are situated from 15 to 20 leagues S.W. of Christiania, in a mountainous country near the city of Kongsberg, which owes to them its population. Their discovery goes back to the year 1623, and their objects are veins of carbonate of lime, accompanied with asbestos and other substances in which native silver occurs, usually in small threads or networks, and sometimes in considerable masses, along with sulphuret of silver. These veins are very numerous, and run through a considerable space, divided into four districts (arrondissements), each of which contains more than 15 distinct explorations. When a new mine is opened, an excavation in the open air is first made, which embraces several veins, and they then prosecute by subterranean workings only those that appear to be of consequence. The workings do not exceed 1,000 feet in depth. Fire is employed for attacking the ore. In 1782, the formation of a new gallery of efflux was commenced, destined to have a length of 10,000 yards, and to cost 60,000*l*. These mines, since their discovery till 1792, have afforded a quantity of silver equivalent to four millions of pounds sterling. The year 1768 was the most productive, having yielded 38,000 marcs of silver. At present they give but a very slender return; in 1804 they were threatened with a complete abandonment. The ore is treated by fusion; the lead necessary for this operation being imported from England. There are, however, lead and silver mines in the county of Järlsberg, but they are very slenderly worked.

At *Edswald*, 50 leagues N. of Christiania, a mine is worked of auriferous pyrites, with a very inconsiderable product.

Cobalt mines may be noticed at Modum or Fossum, 8 leagues W. of Christiania; they are extensive, but of little depth.

Lastly, graphite is explored at *Englidal*; and chromite of iron deposits have been noticed in some points of Norway.

The irons of Sweden enjoy a merited reputation, and form one of the chief objects of the commerce of that kingdom. Few countries, indeed, combine so many valuable advantages for this species of manufacture. Inexhaustible deposits of iron ore are placed amid immense forests of birches and resinous trees, whose charcoal is probably the best for the reduction of iron. The different groups of iron mines and forges form small districts of wealth and animation in the midst of these desolate regions.

The province of Wermeland, including the north bank of the lake Wener, is one of the richest of Sweden in iron mines. The two most important are those of Nordmark, 3 leagues N. of Philipstadt, and those of Persberg, $2\frac{1}{2}$ leagues E. from the same city. Philipstadt is about 50 leagues W. $\frac{1}{4}$ N.W. from Stockholm. Both mines are opened on veins or beds of black oxide of iron several yards thick, directed from N. to S. in a ground composed of hornblende, talcose, and granitic rocks. These masses are nearly vertical, and are explored in the open air to a depth of 130 yards. Formerly this exploitation was effected by iron wedges and pickaxes; but they have been superseded by gunpowder, since 1650. The province of Wermeland, and that of Dahl which adjoins it, forming the west border of the Wener lake, contained in 1767, 48 smelting cones, each going from 4 to 5 months every year.

The principal iron mines of Rosslagie (part of the province of Upland) are those of Dannemora, situated 11 leagues from Upsal. They stand in the first rank of those of Sweden, and even of Europe. The masses worked upon are flattened and vertical, running from N.E. to S.W., and are incased in a ground formed of primitive rocks, among which gneiss, petrosilex and granite are most conspicuous. They amount to three in number, very distinct, and parallel to each other; and are explored through a length of more than 1,500 yards, and to a depth of above 80, by the employment of fire, and blasting with gunpowder. The explorations are mere quarries; each presenting an open trench 65 yards wide, by a much more considerable length, and an appalling depth. Magnetic iron ore is extracted thence, which furnishes the best iron of Sweden and Europe; an iron admirably qualified for conversion into steel. In 1767, these minings supplied for a long time, 15 smelting cones situated in Rosslagie, at a distance of 10 leagues.

The island of Utöe, situated near the coast of the province of Upland, presents also rich iron mines. The protoxide of iron there forms a thick bed in the gneiss. It is worked in trenches far below the level of the sea. The ore can not be smelted in the island itself; but is transported in great quantities to the continent.

The province of Smoland includes also very remarkable mines. Near Jonköping, a hill called the *Taberg* occurs, formed in a great measure of magnetic black oxide of iron, contained in a greenstone reposing on gneiss.

In several parts of Lapland, the protoxide of iron occurs in great beds, or immense masses. At Gellivara, 200 leagues N. of Stockholm, toward the 67th degree of latitude, it constitutes a considerable mountain, into which an exploitation has been opened. The iron is despatched on small sledges drawn by reindeer to streams which fall into the Lutea; and thence by water carriage to the port of Lutea, where it is embarked for Stockholm.

There are a great many iron works in Dalecarlia, but a portion of the ores are got from alluvial deposits. Similar deposits exist also in the provinces of Wermeland and Smoland.

The mines and forges of Sweden produce annually about 165 millions of pounds avoird. (74,000 tons nearly) of cast iron or bar iron; of which two thirds are exported chiefly from the harbors of Stockholm, Gottenburg, Gefle, and Norkoping.

The copper mines of Sweden are scarcely less celebrated than its iron mines. The principal is that of Fahlun or Kopparberg, situated in Dalecarlia, near the town of Fahlun, 40 leagues N.W. of Stockholm. It is excavated in an irregular and very powerful mass of pyrites, which in a great many points is almost entirely ferruginous, but in others, particularly near the circumference, it includes a greater or less portion of copper. This mass is enveloped in talcose or hornblende rocks. More to the west there are three other masses almost contiguous to each other, which seem to bend in an arc of a circle around the principal mass. They are explored as well as the last. This was at first worked in the open air; but imprudent operations having caused the walls to crumble and fall in, since 1647 the excavation presents near the surface nothing but frightful precipices. The workings are now prosecuted by shafts and galleries into the lower part of the deposit, and have arrived at a depth of 194 fathoms (nearly 430 yards). They display excavations spacious enough to admit the employment of horses, and the establishment of forges for repairing the miners' tools. It is asserted that the exploration of this mine goes back to a period anterior to the Christian era. During its greatest prosperity it is said to have produced 11 millions of pounds avoird. of copper per annum, or about 5,000 tons. It furnishes now about the seventh part of that quantity; yielding at the same time about 70,000 lbs. of lead, with 50 marcs of silver, and 3 or 4 of gold. The ores smelted at Fahlun produce from 2 to 2½ of copper per cent. But the extraction of the metal is not the sole process; the sulphur is also procured; and with it, or the pyrites itself, sulphuric acid and other chemical products are made. Round Fahlun, within the space of a league, 70 furnaces or factories of different kinds may be seen. The black copper obtained at Fahlun is converted into rose copper, in the refining hearths of the small town of *Ofwostad*.

In the copper mine of *Garpenberg*, situated 18 leagues from Fahlun, there occur 14 masses of ore quite vertical, and parallel to each other, and to the beds of mica-slate or talc-slate, amid which they stand. This mine has been worked for more than six hundred years.

The mine of *Nyakopparberg*, in *Nericia*, 20 leagues W. of Stockholm, presents masses of ores parallel to each other, the form and arrangement of which are very singular. It is worked by open quarrying, and with the aid of fire.

We may notice also the copper mines of *Atwidaberg*, in *Ostrogothia*, which furnish annually the sixth part of the whole copper of Sweden.

There are several other copper mines in Sweden. Their whole number is ten; but it was formerly more considerable. They yield at the present day in all, about 2,420,000 lbs. avoird. (1000 tons) of copper.

The number of the silver mines of Sweden has in like manner diminished. In 1767 only 3 were reckoned under exploration, viz., that of *Hellefors*, in the province of *Wermeland*; that of *Segersfors*, in *Nericia*; and that of *Sahla* or *Sahlberg*, in *Westmannia*, about 23 leagues N.W. of Stockholm. The last is the only one of any importance. It is very ancient, and passes for having been formerly very productive, though at present it yields only from 4,000 to 5,000 marcs of silver per annum. Lead very rich in silver is its principal product. It is explored to a depth of more than 200 yards. The soundness of the rock has allowed of vast excavations being made in it, and of even the galleries having great dimensions; so that in the interior of the workings there are winding machines, and carriages drawn by horses for the transport of the ores.

At *Sahlberg*, there are deposits of sulphuret of antimony.

For the last 30 or 40 years mines of cobalt have been opened in Sweden, principally at *Tunaberg* and *Los*, near *Nyköping*, and at *Otward* in *Ostrogothia*. The first are worked upon veins of little power, which become thicker and thinner successively; whence they have been called *bead-veins*. It appears that the products of these mines, though of good quality, are inconsiderable in quantity.

Lastly there is a gold mine in Sweden; it is situated at *Adelfors*, in the parish of *Alsfeja*, and province of *Smoland*. It has been under exploration since 1737, on veins of auriferous iron pyrites, which traverse schistose rocks; presenting but a few inches

of ore. It formerly yielded from 30 to 40 marcs of gold *per annum*, but for the last few years it has furnished only from 3 to 4.

The mines and smelting works of Sweden gave annually, in 1809, a gross product worth 1,463,600*l*.

The south of Finland and the bordering parts of Russia contain some mines, but they are far from having any such importance as those of Sweden.

At Orijerwy, near Helsingfors, a mine of copper occurs whose gangue is carbonate of lime, employed as a limestone.

Near Cerdopol, a town situated at the N.W. extremity of the Ladoga lake, veins of copper pyrites were formerly mined.

Under the reign of Peter the Great, an auriferous vein was discovered in the granitic mountains which border the eastern bank of the lake Ladoga, near Olonetz. It was rich only near the surface; and its working was soon abandoned.

Latterly an attempt has been made to mine copper and iron ores near Eno, above and to the N.W. of Cerdopol, but with little success.

Some time ago rich ores of iron, lying in veins, were worked near the lake Shuyna, N.W. from Cerdopol; but this mine has been also relinquished.

On the west bank of the Onega lake, there is an iron work at Petrazavodsk, called a *zavode*, which is the greatest establishment of this kind existing in the north of Russia.

Nothing is now reduced there except bog iron ore, or swamp ore extracted from small lakes in the neighborhood.

The transition limestone which constitutes the body of Esthonia contains lead ore at *Arossaar* near *Fellin*. These ores were worked when these provinces belonged to the Swedes. It was attempted in 1806 to resume the exploitation, but without success.

MINES OF THE ALLEGANY MOUNTAINS.

The chain of the Alleghany, which traverses the United States of North America from N.W. to S.E. parallel to the coasts of the Atlantic ocean, includes a considerable number of deposits of iron, lead, and copper ores; along with some ores of silver, plumbago, and chromite of iron. Attempts have been made to mine a great many of these deposits; but most of these have been unsuccessful.

A bed of black oxide of iron occurs in gneiss near Franconia in New Hampshire. It has a power of from 5 to 8 feet; and has been mined through a length of 200 feet, and to a depth of 90 feet. The same ore is found in veins in Massachusetts and Vermont, accompanied by copper and iron pyrites. It is met with in immense quantities on the western bank of the lake Champlain, forming beds of from 1 to 20 feet in thickness, almost without mixture, encased in granite. It is also found in the mountains of that territory. These deposits appear to extend without interruption from Canada to the neighborhood of New York, where an exploration on them may be seen at Crown Point. The ore there extracted is in much esteem. Several mines of the same species exist in New Jersey. The primitive mountains which rise in the north of this state near the Delaware, include a bed almost vertical of black oxide of iron, which has been worked to 100 feet in depth. In the county of Sussex the same ore occurs, accompanied with Franklinite. At New Milford, in Connecticut, a pretty abundant mine of sparry iron occurs; the only one of the kind known in the Alleghany. The United States contain a great many iron works, some of which prior to the year 1773, sent over iron to London. They are principally supplied from alluvial iron ore.

The most remarkable lead mines of the Alleghany are those of Southampton, in Massachusetts, and of Perkiomen creek, in Pennsylvania, 8 leagues from Philadelphia. The first furnishes a galena, slightly argentiferous; an ore accompanied with various minerals, with base of lead, copper, and zinc, and with *gangues* (vein-stones) of quartz, sulphate of baryta, and fluor spar. These substances form a vein which traverses several primitive rocks, and is said to be known over a length of more than 6 leagues. At Perkiomen creek a vein of galena is mined which traverses a sandstone, referred by many geologists to the old red sandstone. Along with galena a great variety of minerals is found with a basis of lead, zinc, copper, and iron. The mines of lead worked in Virginia, on the banks of the Kanahwa, deserve also to be mentioned.

None of the copper mines actually in operation in the United States seem to merit particular attention. The mine of Schuyler, in New Jersey, had excited high hopes, but after the workings had been pushed to a depth of 300 feet, they have been for some years abandoned. The ore, which consisted of sulphuret of copper, with oxide and carbonate of copper, occurred in a red sandstone.

In some points of the Alleghany, deposits have been noticed of chromite of iron and graphite.

Coal-measures occur in several points of the United States, especially on the N.W.

slope of the Allegany mountains. The coal is mined successfully on the banks of the Ohio, toward the upper part of its course. See ANTHRACITE.

MINES OF THE SOUTH OF SPAIN.

The mountains which separate Andalusia from Estremadura, Leon and La Mancha, and those of the kingdoms of Murcia and Grenada, include some celebrated mines.

We shall mention first the silver mines of *Guadalcanal* and *Cazalla*, situated in the Sierra-Morena, 15 leagues north of Seville. Among the ores, red silver and argentiferous gray copper have been specified. Their product is inconsiderable; but this territory presented formerly much more important mines at *Villa-Guttiera*, not far from Seville. At the beginning of the seventeenth century they are said to have been worked with such activity, that they furnished daily 170 marcs of silver. More to the east, there exists in the mountains of La Mancha a mine of antimony, at *Santa-Crux-de-Mudela*. On the southern slope of the Sierra-Morena, very important lead mines occur, particularly at *Linares*, 12 leagues north of Jaen. The veins are very rich near the surface, which causes them not to be mined much in depth; so that the ground is riddled, as it were, with shafts. More than 5,000 old and new pits may be counted, the greater part of which is ascribed to the Moors. Six of these mines are now explored on account of the crown, and they produce on an annual average, according to M. Laborde, 1,320,000 lbs. of void. (about 600 tons) of lead, which is too poor in silver for this precious metal to be extracted with advantage. Bowles states that there was found at the mines of *Linares*, a mass of galena, whose dimensions were from 21 to 24 yards in every direction. Abundant mines of zinc occur near *Alcaras*, 15 leagues northwest of *Linares*, which supply materials to a brass manufactory established in that town. There are also lead mines in the kingdoms of Murcia and Grenada. Very productive ores have been worked for some time near *Almeira*, a harbor situated some leagues to the west of the cape of *Gates*. The ore is in part treated on the spot with coal brought from *Newcastle*, and in part sent to *Newcastle* to be reduced there. The kingdoms of Murcia, Grenada, and Cordova, include several iron mines. Near *Cazalla* and *Ronda*, in the kingdom of Grenada, mines of plumbago are explored.

On the northern flank of the Sierra-Morena, lie the famous quicksilver mines of *Almaden*, situated near the town of the same name in La Mancha. They consist of very powerful veins of sulphuret of mercury, which traverse a sandstone, evidently of a geological age as old at least as the coal formation. Hard by, beds of coal are mined.

MINES OF THE PYRENEES.

The Pyrenees, and the mountains of Biscay, of the Asturias, and the north of Galicia, which are their prolongation, are not very rich in deposits of ores: the only important mines that occur there, are of iron; which are widely spread throughout the whole chain, except in its western extremity. We may mention particularly in Biscay, the mine of *Sommo-rostro*, opened on a bed of red oxide of iron; and in the province of Guipuseoa, the mines of *Mundragon*, *Oyarzun*, and *Berha*, situated on deposits of sparry iron. There are several analogous mines in Aragon and Catalonia. In the French part of the Pyrenees, veins of sparry iron are worked which traverse the red sandstone of the mountain *Ustelletguy*, near *Baygorry*, department of the Basses-Pyrenees. The same department affords in the valley of *Asson* the mine of *Haugaron*, which consists of a bed of hydrate of iron, subordinate to transition limestone. The deposit of hydrate of iron, worked for an immemorial time at *Rancié*, in the valley of *Viedessos*, department of the *Arriège*, occurs in a similar position. The ancient workings have been very irregular and very extensive; but the deposit is still far from being exhausted. There are also considerable mines of sparry iron at *Lapinouse*, at the tower of *Batera*, at *Escaron*; and at *Pillols*, at the foot of the *Canigou*, in the department of the *Oriental Pyrenees*. The iron mines of the Pyrenees keep in activity 200 Catalanian forges. Although there exists in these mountains, especially in the part formed of transition rocks, a very great number of veins of lead, copper, cobalt, antimony, &c., one can hardly mention any workings of these metals; and among the abandoned mines, the only ones which merit notice are—the mine of argentiferous copper of *Baygorry*, in the department of the *Low Pyrenees*, the lead and copper mine of *Aulus*, in the valley of the *Erce*, department of the *Arriège*, and the mine of cobalt, of the valley of *Gistain*, situated in Aragon, on the southern slope of the Pyrenees. It is asserted, however, that a lead mine is in actual operation near *Bilboa*, in Biscay. The mines of plumbago opened at *Sahun*, in Aragon, should not be forgotten. Analogous deposits are known to exist in the department of the *Arriège*, but they are not mined.

MINES OF THE ALPS.

The mines of the Alps by no means correspond in number and richness with the extent and mass of these mountains. On their eastern slope, in the department of the

high and the low Alps, several lead and copper mines are mentioned, all inconsiderable and abandoned at the present time, with the exception of some workings of galena, which furnish also a little graphite.

During some of the last years of the eighteenth century, there was mined at *la Gardette* in the *Oisans*, department of the *Isère*, a vein of quartz which contained native gold and auriferous pyrites; but the product has never paid the expenses, and the mine has been abandoned. The *Oisans* presented a more important mine, but it also has been given up; it was the silver mine of *Allemont* or *Chalanches*. The ore consisted of different mineral species more or less rich in silver, disseminated in a clay which filled the clefts and irregular cavities in the middle of talcose and hornblende rocks. This mine yielded annually toward the conclusion of the eighteenth century, so much as 2,000 marcs of silver, along with some cobalt ore. Among the great number of mineral species, which occurred in too small quantities to be worked to advantage, there was native antimony, sulphuret of mercury, &c. The *Oisans* present, moreover, some rather unproductive mines of anthracite. Mines of an analogous nature, but more valuable, are in activity at the western foot of the Alps, at *la Mothe*, *Notre-des-Vaux* et *Putterville*, a few leagues southeast of *Grenoble*.

From the entrance of the valley of the *Oisans* to the valley of the *Arc* in *Savoy*, there occur on the N.W. slope of the Alps, a great many mines of sparry iron. The locality of this ore is here very difficult to define. It appears to form sometimes beds or masses, and sometimes veins amid the talcose rocks. Some is also found in small veins in the first course of the calcareous formation which covers these rocks. These mines are very numerous; the most productive occur united in the neighborhood of *Allevard*, department of the *Isère*, and of *Saint Georges d'Hurelières* in *Savoy*. Those of *Forneaux* and *Laprat*, in the latter country, are also mentioned. The irregularity of the mining operations surpasses that of the deposits; the mines have been from time immemorial in the hands of the inhabitants of the adjoining villages, who work in them, each on his own account, without any prearrangement, or other rule than following the masses of ore which excite hopes of the most considerable profit in a short space of time. What occurs in almost every mine of sparry iron, is also to be seen here—most imprudent workings. The mine called the *Grand Fosse*, at *Saint Georges d'Hurelières*, is prolonged without pillars or props, through a height of 130 yards, a length of 220 yards, and a breadth equal to that of the deposit, which amounts in this place to from 8 to 13 yards; thus a void space is exhibited of nearly 300,000 square yards. The sparry iron extracted from these different mines supplies materials to 10 or 12 smelting-furnaces, the cast-iron of which, chiefly adapted for conversion into steel, is manufactured in part in the celebrated steel works of *Rives*, department of the *Isère*. There occurs in some parts of the mines of *Saint Georges d'Hurelières* copper pyrites, which is smelted at *Aiguebelle*.

Savoy presents celebrated lead mines at *Pessey* and at *Macot*, 7 leagues to the east of *Moutiers*. Galena, accompanied with quartz, sulphate of baryta, and ferriferous carbonate of lime, occurs in mass in talcose rocks. The mine of *Pessey* had been restored to activity by the French government, which established there a practical school of mines; and in its hands the mine produced annually as much as 440,000 lbs. avoird. of lead, and 2,500 marcs of silver. It is now explored on account of the king of *Sardinia*; but it begins to be exhausted, and yields less products. That of *Macot*, opened a few years ago, begins to give considerable returns. The mine of copper pyrites of *Servoz*, in the valley of the *Arve*, may also be mentioned. The ore occurs both in small veins, and disseminated in a clay slate; but the exploration is now suspended. Lastly, slightly-productive workings of anthracite are mentioned in several points of these mountains, and in the continuous portions of the Alps.

There exist in *Piedmont* some small mines of argentiferous lead. The copper mines of *Allagne*, and those of *Ollomont*, formerly yielded considerable quantities of this metal. Their exploration is now on the decline. The manganese mines of *Saint-Marcel* have few outlets; whence they have been feebly developed. Mines of plumbago, little worked, occur in the neighborhood of *Vinay*, and in the valley of *Pellis*, not far from *Pignerol*. Some mines of auriferous pyrites have also been worked in this district of country; among others, those of *Macugnaga*, at the eastern foot of *Monte-Rosa*. The pyrites of this mine afforded by amalgamation only 11 grains of gold per quintal; and this gold, far from being fine, contained one fourth of its weight of silver; they became less rich in proportion as they receded from the surface. The explorations of auriferous pyrites in *Piedmont* are now abandoned, or nearly so. The only important mines in this country are those of iron. These generally consist of masses of black oxide of iron, of a nature analogous to those of *Sweden*; the principal ones being those of *Cogne* and *Traverselle*, which are worked in open quarries. Some others, less considerable, are explored by shafts and galleries. These ores are reduced in 33 smelting-cupolas, 55 *Catalan* forges, and 105 refinery-hearths. The whole produce about 10,000 tons of bar-iron.

There is a mine of black oxide of iron, at present abandoned, at *Bovernier*, near *Martigny*, in the *Valais*. There is also another iron mine at *Chamoissons*, in a lofty calcareous mountain on the right bank of the *Rhone*. The ore presents a mixture of oxide of iron and some other substances, of which it has been proposed to make a new mineral species, under the name of *Chamoissite*.

The district of the *Grisons* possesses iron mines with very irregular workings, situated a few leagues from *Coire*.

The mountain of *Falkenstein*, in the *Tyrol*, formed of limestone and clay-slate, not far from *Schwatz*, a little below *Innsbruck*, in the valley of the *Inn*, contains mines of argentiferous copper. At one of them, that of *Kütz-Pühl*, the workings reached, in 1759, according to the report of *MM. Jars* and *Duhamel*, nearly 1,100 yards in depth; and were reckoned the deepest in Europe. But it was intended to abandon them. Analogous ores are explored in several other points of the same country. The most part of the products of these mines are carried to the foundry of *Brixlegg*, 4 leagues from *Schwatz*. The mines of the *Tyrol* furnished, on an average of years, toward 1759, 10,000 marcs of silver; at anterior periods, their products had been double; but now it is a little less. This region contains also gold mines whose exploration goes back a century and a half. They occur near the village of *Zell*, 8 leagues from *Schwatz*; the auriferous veins traverse clay-slates and quartz rocks. Lastly, a deposit of oxide of chrome, similar to that of the *Ecouchets* (*Saône* and *Loire*) has been discovered in the *Tyrol*. An unimportant mine of mercury has also been mentioned in that country, near *Brenner*.

In the territory of *Salzburg* there are some copper mines. In the environs of *Muerwinkel* and of *Gastein* some veins are worked for the gold they contain; of which the annual return is valued at 118 marcs of this metal. There is an inconsiderable mine of quicksilver at *Leogang*.

In the *Tyrol* and in *Salzburg* there are iron mines in a very active state, principally those of *Kleinboden*, near *Schwatz*. But the portion of the Alps most abundant in mines of this metal, is the branch stretching toward Lower Austria. We find here, both in *Styria* and in *Austria*, a very great number of explorations of sparry iron. The deposits of the ores of sparry iron of *Eisenerz*, *Erzberg*, *Admont*, and *Vordenberg*, deserve notice. The latter are situated about 25 leagues southwest of *Vienna*.

The southern flank of the Alps contains also a great many mines of the same kind, from the *Lago Maggiore* to *Carinthia*. Those situated near *Bergamo*, and those of *Huttenberg* and *Waldenstein*, in *Carinthia*, are especially mentioned.

All these mines of sparry iron are opened in the midst of rocks of different natures, which belong to the old transition district of the Alps. They seem to have close geological relations with those of *Allevard*.

The branch of the Alps which extends toward Croatia, presents important iron mines, in the mountains of *Adelsberg*, 10 leagues southwest from *Laybach*, in *Carniola*.

The iron mines just now indicated in the part of the Alps that forms a portion of the Austrian states, supply materials to a great many smelting-works. In *Styria* and in *Carinthia*, more than 400 furnaces or forges may be enumerated, whose annual product is nearly 25,000 tons of iron. These two provinces are famous for the steel which they produce, and for the steel tools which they fabricate, such as sythes, &c. *Carniola* contains also a great many forges, and affords annually about 5,000 tons of iron.

There are mines of argentiferous copper, analogous to those of the *Tyrol*, at *Schladming* in *Styria*, at *Kirchdorf* in *Carinthia*, at *Agordo* in the territory of *Venice*, and at *Zamabor* in *Croatia*. The latter are remarkable for the great irregularity of the deposits, and for the richness of the copper pyrites that is mined; which produces 12 and sometimes 27 per cent. of copper. There are some deposits of antimony, mined to a trifling extent in *Carinthia*; and there are a few cobalt mines in *Styria*, not more actively worked. In the environs of *Raibell*, in *Carinthia*, mines of calamine exist, yielding annually about 200 tons of this substance. Of late, some of it has also been explored in *Styria*.

The limestones that cover the northern slopes of the Alps, present, like those of the departments of the lower and upper Alps, several lead mines of little consequence; they also include several celebrated mines of rock salt.

The analogous limestones which repose on the slopes of the Alps in *Carinthia*, and in the neighboring provinces, afford likewise lead mines, especially near *Willach* and *Bleyberg*. These mines are very numerous, forming more than 500 *arrondissements* of concessions. They furnish annually about 1,800 tons of a lead too poor in silver to pay the expense of extracting that precious metal. At the mines of *Bleyberg*, the galena forms 14 beds or strata, inclined at an angle of from 40 to 50 degrees from the horizon, and alternating with a like number of calcareous strata. The latter are extremely full of shells. They of course belong to secondary limestone.

The limestones surmounting the southern slope of the Alps, contain also some lead mines; but the quicksilver mines of Idria, situated at the foot of the Alps, 10 leagues N.W. of Trieste, is worthy of particular notice; it lies in a limestone which everything leads us to refer to the *zechstein*, the most ancient of the secondary limestones.

The Apennines, which may be considered as a dependance of the Alps, present a small number of mines. At Chiavary and Pignone, manganese is mined; and at the beginning of the eighteenth century a vein of mercury was worked at Levigliani in Tuscany. An antimonial mine is mentioned at Pereta in the marshes of Sienna.

Before quitting these regions, we ought to notice the iron mines of the isle of Elba. They have been famous for 18 centuries; Virgil denotes them as inexhaustible, and supposes them to have been open at the arrival of *Æneas* in Italy. They are explored by open quarries, working on an enormous mass of specular iron ore, perforated with cavities bespangled with quartz crystals. The island possesses two explorations, called Rio and Terra-Nuova; the last having been brought into play at a recent period. The average amount extracted per annum is 15,000 tons of ore, which are smelted in the foundries of Tuscany, Liguria, the Roman states, the kingdom of Naples, and the island of Corsica.

There has been worked for a few years a mine of chromite of iron, at Carrada, near Gassino, department of the Var.

MINES SITUATED IN THE SCHISTOSE FORMATIONS OF THE BANKS OF THE RHINE, AND IN THE ARDENNES.

The transition lands, which form, in the northwest of Germany and in Flanders, a pretty extensive range of hills, include several famous mines of iron, zinc, lead, and copper. The latter lie on the right bank of the Rhine, in the territories of Nassau and Berg, at Baden, Augstbach, Rheinbreitenbach, and near Dillenburg. That of Rheinbreitenbach yielded formerly 110,000 lbs. *avoirdupois* of copper per annum, and those of the environs of Dillenburg now furnish annually 176,000 lbs. There are also some mines of argentiferous lead in the same regions. The most remarkable are in the territory of Nassau, such as those of Holzapfel, Pfingstviere, Löwenburg, and Augstbach on the Wiede, and Ehrental on the banks of the Rhine, which all together produce 600 tons of lead, and 3,500 marcs of silver. To the above, we must add those of the environs of Siegen and Dillenburg, in the territories of Berg. A little cobalt is explored in the neighborhood of Siegen, and some mines of the same nature are mentioned in the grand dutchy of Hesse-Darmstadt, and in the dutchy of Nassau Usingen.

But iron is the most important product of the mines on the right bank of the Rhine. Veins of hydrate of iron, or brown hematite, are explored in a great many points of Hessa, and the territory of Nassau, Berg, Marck, Tecklenbourg, and Siegen, along with veins or masses of sparry iron, and beds of red oxide of iron. We may note particularly—1. The enormous mass of sparry iron, known under the name of *Stahlberg*, mined since the beginning of the fourteenth century in the mountain of Martinshardt, near Müssen, where improvident excavations have occasioned, at several times, considerable downfallings of rubbish; 2. The abundant and beautiful mines of hydrate of iron and sparry iron on the banks of the Lahn and the Sayn, and among those of the mine of Bendorf; 3. The mine of Hohenkirchen in Hessa, where a powerful bank of manganese ore is worked, and where the mines are kept dry by a gallery more than 1,000 yards long, walled over its whole extent. These several mines supply a great many iron works, celebrated for their steel, and for the objects of hardware, sythes, &c., fabricated there.

The Prussian provinces of the left bank of the Rhine, the dutchy of Luxembourg, and the Low Countries, include also many iron furnaces, of which a great number are supplied, in whole or in part, by ores of hydrate of iron, occasionally zinciferous, extracted from the transition rocks, where they form sometimes veins, and sometimes also very irregular deposits. A portion is explored by open quarrying, and a portion by underground workings. Some of these mines penetrate to a depth of 87 yards, and galleries may be observed in them cut in the form of vaults, and timbered with hooped stays. The Hundsrück, the Eiffel, and the territory of Luxembourg, present a great many of them.

The Eiffel formerly possessed important lead mines. Some still exist, which are feebly worked at Berncastelle, 8 leagues below Trèves, on the banks of the Moselle. Those of Trarbach, situated 2 leagues lower, are now completely abandoned; the same holds with those of Bleyalf, which were opened on veins incased in the greywacke-slate, 3 leagues W.N.W. of Prüm, not far from the line of separation of the waters of the Moselle and the Meuse, in a district from which manufactures and comfort have disappeared since the mines were given up which sustained them.

More to the north a great many deposits of calamine occur. The most considerable

and the one explored with most activity, is situated in the territory of Limburg (kingdom of the Netherlands), and known under the name of the *Great mountain*. It presents a mass about 45 yards wide, from 400 to 550 long, and of an unknown depth. The first labors, undertaken several centuries ago by the Spaniards, were executed by open quarrying, and pushed down 32 yards from the surface. The miners were obliged to renounce this mode of operation, and have since penetrated to the depth of 88 yards by means of subterranean workings. From 50 to 60 men work in this excavation, and exact annually from 700 to 800 tons of calamine, worth from 2,400*l.* to 2,700*l.* In the adjacent parts of the Prussian territory, not far from Aix-la-Chapelle, calamine is also mined, with ores of lead and iron, with which it is associated, in deposits regarded by M. Bouesnel, as analogous to the vein of Vedrin, to be noticed presently. The exploration is effected by means of small round shafts, from 34 to 44 yards deep, which are often wooded only with flexible branches of trees, or a kind of barrel-hoops. These workings may furnish annually from 1,500 to 2,000 tons of calamine, to the brass factories of Stollberg. On the right bank of the Rhine, in the country of la Marek, several small zinc mines furnish annually about 130 tons of calamine to the brass manufactures of Iserlohn.

The lead mine of Fedrin, alluded to above, lies at some distance N. of Namur. It is opened on a vein of galena nearly vertical, which crosses from N. to S. a limestone in nearly vertical strata, probably analogous into the limestone of Derbyshire. The vein is from 4 to 15 feet thick, and is recognised through a length of half a league. The mine, worked for two centuries, presents very extensive excavations; particularly a fine gallery of efflux. It has produced annually 900 tons of lead. At the present day the mine of Vedrin, and some adjoining exploitations, afford per annum only about 200 tons of lead, and 700 mares of silver.

MINES OF THE CALCAREOUS MOUNTAINS OF ENGLAND.

The limestone formation immediately subjacent to the coal measures, or the mountain limestone, constitutes almost alone several mountainous regions of England and Wales; in which three districts very rich in lead mines deserve to be noted.

The first of these districts comprehends the superior parts of the valleys of the Tyne, the Wear, and the Tees, in the counties of Cumberland, Durham, and York. Its principal mines are situated near the small town of Alston-Moor, in Cumberland. The veins of galena which form the object of the workings, traverse alternate beds of limestone and sandstone; and are very remarkable for their becoming suddenly thin and impoverished on passing from the limestone into the sandstone; and for resuming their richness, and usual size, on returning from the sandstone into the limestone. The exploitations are situated in the flanks of considerably high hills, bare of wood, and almost wholly covered with marshy heaths. The waters are drawn off by galleries of efflux; and the ores are dragged out by horses to the day. The galena extracted from these mines is smelted by means of coal and a little peat, in furnaces of the Scotch construction. The lead is very poor in silver; and there is hardly a single hearth for the purpose of eliminating this metal by cupellation. The mines of this district produce annually 17,200 tons of lead, according to Mr. Taylor's statement, published in the *Geology of England and Wales*, by Messrs. Conybeare and Phillips. There is more over a copper-mine 2 leagues S.W. of Alston-Moor. The ore is a copper pyrites, accompanied with galena in a very extensive vein, which does not appear to belong to the same formation as the other veins of this region.

The second metalliferous district lies in the northern part of Derbyshire, and in the contemurinous parts of the neighboring counties. The districts called the Peak and King's-Field are the richest in workable deposits. The mines of Derbyshire are getting exhausted; they are very numerous, but in general inconsiderable. The galena extracted from them is treated with coal in reverberatory furnaces; but the silver is not sought for. They yield annually 900 tons of lead; with a certain quantity of calamine, and a little copper ore. A vein of copper pyrites occurs at Ecton, in Staffordshire, on the borders of Derbyshire. The veins of Derbyshire are famous for the beautiful minerals which they have produced; and particularly for the interruption which they almost constantly suffer at the contact of the trap-rock, called toadstone, which is intruded among the limestone.

The third metalliferous district is situated in Flintshire and Denbighshire, counties forming the N.E. part of Wales. Next to Alston-Moor this is the most productive; furnishing annually 6,900 tons of lead, and a certain quantity of calamine. The galena is smelted in reverberatory furnaces, and affords a lead far from rich in silver, which is therefore seldom subjected to cupellation. The mines occur partly in the metalliferous limestone, and partly in several more ancient rocks.

To the S.E. of this district there exist still some lead mines in Shropshire. They

lie, like the preceding, partly in the metalliferous limestone, and partly in the subjacent rocks. They yield annually from 700 to 800 tons of lead.

Some mines of galena and calamine are mentioned in the Mendip hills, to the south of Bristol; but they seem to be for the present abandoned.

Besides the metallic mines just enumerated, the formation of the metalliferous limestone presents, in England, especially in the counties of Northumberland and Cumberland, several coal mines, opened on coal strata included by the sandstone, which alternates with the limestone.

MINES OF DAOURIA.

The name Daouria is given to a great region wholly mountainous, which extends from the Baikal Lake to the eastern ocean. There is, perhaps, no other country in the world so rich in deposits of lead ores, as the part of this district which extends from the junction of the rivers Chilca and Argoun, whose united waters form the river Amour, belonging to Russia. The mines opened here constitute the third arrondissement of the Siberian mines, called that of Nertchinsk, from the name of its capital, which lies more than 1,800 leagues east of Saint Petersburg.

The ground of the metalliferous portion of Daouria is formed of granite, hornschiefer, and schists, on which reposes a gray limestone, sometimes siliceous and argillaceous, which contains a small number of fossils, and in which the veins of lead occur. The plains of these regions, often salt deserts, exhibit remarkable sandstones and pudding-stones; as also vesicular rocks of a volcanic aspect. It appears that the metalliferous limestone is much dislocated, and the lead veins are subject to several irregularities, which render their exploitation difficult and uncertain. The mines lie chiefly near the banks of the Chilca and the Argoun, in several cantons, at a considerable distance from one another; wherefore it was requisite to build a great number of smelting furnaces. The want of wood has placed difficulties in the working of some of them. The ore is galena, sometimes occurring in masses of several yards in diameter; having commonly for vein-stones ores of iron and zinc, of which no use is made. The galena itself, furnished by these mines in enormous quantities, receives a very different treatment from what it would do in a civilized country; for, though the lead which it produces contains only from 6 to 10 gros (1 to 1½ ounce) of silver per quintal, it is for it alone that these mines are worked. The litharge produced by the cupellation is thrown away as useless; so that heaps of it exist near the smelting-furnaces, says M. Patrin, higher than the houses. Only an insignificant quantity of it is reduced to lead for the uses of the country, or for those of the foundries in the arrondissement of Kolywan. The silver extracted from the mines of Daouria, contains a very small proportion of gold. M. Patrin says that their annual product was, toward the year 1784, from 30,000 to 35,000 marcs of silver. The exploitation of some of the mines of Daouria goes back to the end of the 17th century. It has been commenced in some points by the Chinese, who were not entirely expelled from this territory till the beginning of the following century. A great part of the mines, however, has been opened up since 1760.

Besides the lead mines, there are some unimportant mines of copper in Daouria, and in different explorations of this region, arsenical pyrites, from which arsenious acid is sublimed in factories established at Jutlack and at Tchaltchinsky.

About 45 leagues to the south of Nertchinsk, the mountain of Odon-Tchelon occurs, celebrated for the different gems or precious stones extracted from it. It is formed of a friable granite, including harder nobules or balls which enclose topazes; it is very analogous to the topaz rock of Saxony. In this granite there are several veins filled with a ferruginous clay, which contains a great quantity of wolfram, and many emeralds, aqua-marines, topazes, crystals of smoked quartz, &c. Multitudes of these minerals have been extracted by means of some very irregular workings. The mountain of Toult-Kaltoui, situated near the preceding, offers analogous deposits. The presence of wolfram had excited hopes that tin might be found in these mountains; hopes which have not hitherto been realized. There are some unworked deposits of sulphuret of antimony in this country.

ON SOME OTHER LESS KNOWN MINE COUNTRIES.

There seem to exist in Brazil, besides the washings of the sands that produce the diamonds, the precious stones, the platinum, and almost all the gold of this country, some mines of gold, lead, and iron, opened up in very ancient geological formations; but there is no silver mine, which indicates a great difference between the metalliferous deposits of this district and those of Spanish America. The lead mines occur particularly in the captainry of Minas-Geraes, canton of Abaité. Their exploitation has been undertaken within a few years. The captainry of Minas-Geraes contains extremely abundant deposits of black oxide of iron, and specular iron, which constitute beds or enormous masses, forming sometimes entire mountains; along with numerous

veins of hematite and red oxide of iron. Lately these have been opened up, and smelting-houses have been established at Gaspar-Saarez. There are also iron mines and foundries in the captainry of Saint-Paul. A mine of antimony occurs near Sabara, in the captainry of Minas-Geraes.

In Africa, the inhabitants of the countries adjoining to the cape of Good Hope mine and smelt copper and iron; and the Congo produces considerable quantities of these two metals. It is asserted that a great deal of copper exists in Abyssinia. On the banks of the Senegal the Moors and the Pouls fabricate iron in travelling forges. They employ as the ore the richest portions of a ferruginous sandstone, which seems to be a very modern formation. Lastly, the kingdoms of Morocco and Barbary appear to include several copper and iron mines.

The islands of Cyprus and Negropont, in the Mediterranean, were celebrated, in former times, for their copper mines; and several islands of the Archipelago presented gold mines, now abandoned. The same thing may be said of Macedonia and Thrace. The mountains of Servia and Albania contain iron mines; and lead mines occur in Servia. Natolia possesses iron and copper mines in the neighborhood of Tokat. Some also occur in Arabia and in Persia; and in the territories round Caucasus, the kingdom of Imeretta is distinguished for its iron mines. The celebrity of the Damascus sabres attests the good quality of the products of some of the mines. Persia includes, besides, mines of argentiferous lead at *Kervan*, a few leagues from Ispahan; and Natolia furnishes orpiment.

Some iron and copper mines have been mentioned in Tartary. Thibet passes for being rich in gold and silver mines. China produces a great quantity of iron and mercury, as well as white brass (*tombac*), which is much admired. The copper mines of this empire lie principally in the province of Yu Nan and the island of Formosa. Japan, likewise, possesses copper mines in the provinces of Kijunnack and Sarunga. They seem to be abundant; at a period not far back, they exported their products to Europe. Japan presents, moreover, mines of quicksilver. China and Japan contain also mines of gold, silver, tin, red sulphuret of arsenic, &c. Large deposits of the latter ore (realgar) are said to occur in the tin mine of Kian-Fu, in China. But in that empire, as in Europe, coal is the most important of the mining products. This combustible is explored, especially in the environs of Pekin, and in the northern parts of the empire.

Iron mines exist in several points of the Burman empire, and of Hindostan. Near Madras there exist excellent ores of sparry iron, and black oxide, analogous to the Swedish ores. The Indian natural steel, named Wootz, has been held in considerable estimation among some eminent London cutlers; but the iron and steel recently manufactured upon a great scale, near Madras, by Messrs. Heath and Co., from the crystallized magnetic ore of that country, will probably ere long rival, and eventually supersede in Europe the product of the Dannemara forges. The islands of Macassar, Borneo, and Timor, include copper mines. As to the tin obtained from the island of Banca, from the peninsula of Malacca, and several other points of southern Asia, it proceeds entirely from the washing of sands. The same is undoubtedly true of the gold furnished by the Philippine isles, Borneo, &c. It appears, however, that mines of gold and silver are worked in the island of Sumatra.

MINES OF THE SECONDARY ROCK FORMATIONS.

The most important mines of the secondary rocks, and perhaps of all minerals whatsoever, are those worked in the most ancient of these strata, in the coal-measures.

The British islands, France, and Germany, present several groups of small mountains primitive on the ridge, and transition on the flanks; in the sinuosities between which deposits of coal occur. The principal of these have become great centres of manufactures; for Glasgow, Newcastle, Sheffield, Birmingham, Saint-Etienne, &c., owe their prosperity and their rapid enlargement to the coal, raised, as it were, at their gates in enormous quantities. Wales, Flanders, Silesia, and the adjacent parts of Galicia, owe equally to their extensive collieries a great portion of their activity, their wealth, and their population. Other coal districts, less rich, or mined on a less extended scale, have procured for their inhabitants less distinguished, but by no means inconsiderable, advantages; such, for examples in Great Britain, are Derbyshire, Cheshire, Lancashire, Shropshire, Warwickshire, the environs of Bristol &c.; some parts of Ireland; in France, Lirzy department of Calvados, Comanterie, Saint-Georges-Chatelaion, Aubin, Alais, le Creusot; Ronchamps, in the Prussian provinces of the left bank of the Rhine; the environs of Saarebrück; several points of the north of the territory of Berg and La-marck, of Mansfeld, of Saxony, Hungary, Spain, Portugal, the United States, &c.

We need not enter here into ampler details on coal mines, reserving these particulars for the article *PIR-COAL*.

Nature has deposited alongside of coal an ore whose intrinsic value alone is very small, but whose abundance in the neighborhood of fuel becomes extremely precious to

man; we allude to the clay-ironstone of the coal-measures. It is extracted in enormous quantities from the coal-basins of Scotland, Yorkshire, Staffordshire, Shropshire, and South Wales.

Much of it is also raised from the coal strata of Silesia; and the French entertain hopes of finding a supply of this necessary ore in their own country. The iron-works of England, which are supplied almost entirely from this iron-stone reduced with the coke or coal, pour annually into commerce more than one million tons of cast and bar iron, the value of which has been estimated at eight millions sterling; an amount fully equal to the product of all the mines of Spanish America.

The shale or slate-clay of the coal-measures contains sometimes a very large quantity of pyrites, which, decomposing by the action of air, with or without artificial heat, produces sulphate of iron and sulphate of alumina; whence copperas and alum are manufactured in great abundance.

The lead mines of Bleyberg and Gemünd, near Aix-la-Chapelle, are explored in a sandstone referred by many geologists to the red sandstone. The ore consists principally of nodules, of galena disseminated in this rock. They are very abundant, and of very easy exploration. These mines produce annually from 700 to 800 tons of lead, which does not contain silver in sufficient proportion to be worth the extracting. 2,000 tons of ore are prepared and sold in the form of black lead dust (*alquifour*).

The manganese mines worked in the open air near Exeter, in England, occur in a sandstone analogous to the red.

The calcareous formation which surmounts the coal-sandstone, called by geologists *zechstein*, magnesian limestone, and older alpine limestone, contains different deposits of metallic ores; the most celebrated being the cupreous schist of Mansfeldt, a stratum of calcareous slate from a few inches to two feet thick, containing copper pyrites in sufficient quantity to afford 2 per cent. of the weight of the ore of an argentiferous copper. This thin layer displays itself in the north of Germany over a length of eighty leagues, from the coasts of the Elbe to the banks of the Rhine. Notwithstanding its thinness and relative poverty, skilful miners have contrived to establish, on different points of this slate, a number of important explorations, the most considerable being in the territory of Mansfeldt, particularly near Rottenburg. They produce annually 2,000 tons of copper, and 20,000 mares of silver. We may also mention those of Hessa, situated near Frankenberg, Bieber, and Riegelsdorf. In the latter, the cupreous schist and its accompanying strata are traversed by veins of cobalt, mined by the same system of underground workings as the schist. These operations are considerable; they extend, in the direction of the strata, through a length of 8,700 yards, and penetrate downward to a very great depth. Three galleries of efflux are to be observed; two of which pour their waters into the Fulde, and the third into the Verra. One of them runs about 20 yards below the most elevated point of the workings. These mines have been in activity since the year 1530. Analogous mines exist near Saalfeld, in Saxony.

To the same geological formation must probably be referred the limestone which contains the sparry iron mine of Schmalcalden, at the western foot of Thuringerwald, where there has been explored from time immemorial a considerable mass of this ore known by the name of *Stahlberg*. The working is executed in the most irregular manner, and has opened up enormous excavations; whence disastrous ruins have taken place in the mines. It furnishes annually 4,500 tons of ore, which keep in play a great number of furnaces, where a deal of iron and steel is manufactured.

At Tarnowitz, 14 leagues S.E. of Oppeln, in Siberia, the *zechstein* contains, in some of its strata, considerable quantities of galena and calamine; into which mines have been opened, that yield annually from 600 to 700 tons of lead, 1,000 to 1,100 mares of silver, and much calamine. Mines of argentiferous lead are noticed at Olkutch and Jaworno, in Galicia, about 6 leagues N.E. of Cracow, and 15 leagues E.N.E. of Tarnowitz. Their position seems to indicate that they belong to the same formation; and possibly those of Willach and Bleyberg in Carinthia have the same locality.

There has been discovered lately near *Confolens*, in the department of *la Charente*, in a secondary limestone, calcareous beds, and particularly subordinate beds of quartz, which contain considerable quantities of galena. At *Figeac* also, in the department of *le Lot*, deposits of galena, blende, and calamine, occur in a secondary limestone. At *la Voulte*, on the banks of the Rhone, there is mined, in the lower courses of the limestones that constitute a great portion of the department of the *Ardèche*, a powerful bed of iron ore.

It is in the *zechstein*, or in the sandstones, and trap rocks of nearly the same age, that the four great deposits of the sulphuret of mercury, of *Idria*, the *Palatinate*, *Almaden*, and *Huancavelica*, are mined.

The formation which separates the *zechstein* from the *lias* (*calcaire a gryphites*), called new red sandstone and red marl in England, and *bunter-sandstein*, *muschelkalk*, and *quadersandstein*. in Germany, presents hardly any important mines except those of rock

salt; which enrich it, not only in the centre of Europe, as in Cheshire, at Vic, Wieliczka, Bochnia, and Salzbourg, but in many other parts of the world.

The lias contains often very pyritous lignites, which are mined in many places, and particularly at Whitby and Guisborough in Yorkshire, for the manufacture of alum and copperas.

The oolitic limestones contain strata of iron ore, which are mined in some districts of France.

The iron sand (Hastings sand) beneath the chalk formation, is often so strongly imbued with iron as to be worth the working.

The lowest beds of the chalk contain iron pyrites, which has become the object of an important exploration at *Vissans*, on the southern coast of the *Pas-de-Calais*, where it is converted into sulphate of iron. The waves turn the nodules out of their bed, and roll them on the shore, where they are picked up.

If the chalk be poor in useful minerals, this is not the case with the plastic clay formation above it; for it contains important mines. In it are explored numerous beds of lignite (wood-coal), either as fuel or a vitriolic earth. From these lignite deposits, also, the yellow amber is extracted.

The other tertiary formations present merely a few mines of iron and bitumen.

Several of the secondary or tertiary strata contain deposits of sulphur, which are mined in various countries.

The formations of a decidedly volcanic origin afford few mining materials, if we except sulphur, alum, and opals.

MINES OF THE ALLUVIAL STRATA.

This formation contains very important mines, since from it are extracted all the diamonds, and almost all the precious stones, the platinum, and the greatest part of the gold, with a considerable portion of the tin and iron. The diamond mines are confined nearly to Brazil, and to the kingdoms of Golconda and Visapour in the East Indies.

MINES, VENTILATION OF. The means adopted in the South Staffordshire coal mines, which have veins varying from 25 to 30 feet in thickness, are well worthy of consideration; since a solid mass of that magnitude must be peculiarly difficult to drain of its imprisoned gas. In excavating such coal large masses must be detached, and pockets or hollows must be formed, which are immediately filled with carburetted hydrogen: whilst a thin vein, for which a level roof can generally be secured, can be kept tolerably free from such accumulations.

In December, 1846, in consequence of a frightful explosion which took place at Oldbury, Mr. Benjamin Gibbons was induced to publish a small work descriptive of the principles of ventilation adopted and practised by him for many years before in the thick and thin mines that were worked under his personal superintendence.

The author first recapitulates the substance of a part of his work, and gives, in addition, the results of an enlarged experience, as well as a slight notice and reply to some of the objections made to his plan.

Carburetted hydrogen gas, which produces these dreadful explosions, is not explosive until it is united with a certain proportion of ordinary air, say seven to nine times its volume; when this mixture has taken place, it arrives at what is termed its "firing" or explosive point; and in that state, if it come in contact with the flame of a candle, it will instantly explode, with similar rapidity and violence to gunpowder. A considerable volume of this gas is set at liberty in all the thick coal mines, when worked in the usual manner, and as often as fresh masses of coal are cut through. Some coal mines supply a much greater quantity of gas than others, and these are commonly called "fiery mines;" but, in all coal mines, a sufficient quantity is extracted to produce the most direful consequences, if it be not neutralized, or its escape duly provided for.

The general mode is that of diluting the gas with a quantity of atmospheric air; and a current of air equal to thirty times the volume of gas yielded by the coal, is, in the author's opinion, the bare limit of safety: that is to say, thirty cubic feet of common air must circulate through the mine in the space of time that the coal will give out one cubic foot of gas; but the quantity of air should exceed this, where this mode of ventilation is practised; for a copious supply of fresh air is needful for the numerous workmen, horses, and candles, employed in the pit.

Many mechanical plans have been recommended to increase the current of air through the mines; in some, force pumps, and in others, exhaust pumps, have been proposed, to produce an artificial current of air throughout the workings. These plans, theoretically, may be very correct, but, it is to be observed, that the current of air must be constantly maintained; and in the practical application, the engine that works these pumps, or other mechanical means, may get out of order, and thereby endanger the lives of all the miners. This fatal objection attaches to all mechanical plans of ventilation; and, indeed, to all artificial modes, where the power of ventilation is not self-acting,—

but requires the constant action of machinery, or the constant aid of men; even including the ordinary plan of rarefaction of the air by a separate fire, which may be out when it ought to be in, and ought not to be relied upon as the sole protector, though it will be, in some circumstances, a useful auxiliary.

We should therefore avail ourselves, as far as possible, of the natural powers that are at our command; and, in this instance, the extreme levity of the gas from which we wish to rid the mines, supplies us, to a considerable extent, with the remedy required. But cases may arise where other auxiliaries may be temporarily required, from accidental misplacements of the level of the mine; although, in the author's opinion, these cases may be reduced to a few, if the mines are opened out and worked upon a proper system, as will be further noticed in this paper. Under these circumstances, it may be necessary to employ heat, to rarefy the upcast current of air, to make it specifically lighter than the downcast; or mechanical means to force air in, or to extract air from the mines, may be required. Where artificial heat is made use of, a steam-jet, from the boiler of the winding-engine, is the most secure method; because, the steam being supplied from the boiler of the winding-engine, it is clear that the steam is always at command whilst the pit is at work. If mechanical means should become necessary, Mr. Struve's exhausting cylinders supply the most powerful and effective apparatus that has fallen under the author's notice.

The object of the present paper is to show that there is a constant self-acting power available, which experience has shown will afford the desired protection in ordinary temperatures, in the majority of cases; because the carburetted hydrogen of the mine being half the weight of common air (it has an equal ascending power to common air heated to 512° , being of the same specific gravity), will rise to the highest parts of the mine, and would escape with great velocity, if permitted to do so; forming, in the aggregate, a very large ascending power, as exemplified in the balloon; but, in the ordinary system of working, this escape is unprovided for, indeed, absolutely prevented.

According to the ordinary system adopted in the collieries of this district, two shafts are sunk, near together, about 7 to 7½ feet in diameter, each to the bottom of the coal, say about 180 yards depth, the two shafts commencing at the same level, and terminating at the same level. One of these becomes the "downcast pit" down which the air descends, and the other the "upcast pit" up which the air ascends, when a communication is made between them at the bottom; but the only determining causes for the motion of the air being accidental, it is unknown beforehand what direction the current will take, and which will become the downcast pit. It is generally found that a current of air does take place (it may almost be said always takes place), without any other means being employed; but the determining power is so faint, that, issuing from the upcast pit with such trifling velocity, it is liable to be deranged by the action of the wind, or by atmospheric changes; and it sometimes happens that the air becomes quiescent, or an unsteady column, alternately ascending and descending the same shaft; and then, in miner's language, the pits "fight," and the air will neither ascend nor descend with regularity in one direction. But worst of all, the course of the air will be sometimes inverted or "turned"—that which should be the downcast pit becoming the upcast; and the mine then becomes exposed to the most fearful results, where the workings have been opened, by the air being driven backwards along the air-head into the reservoirs of gas formed in the upper cavities of the workings, and issuing into the gate-road, charging the gas to the firing point.

The danger of this change in the direction of the air current is increased by the upcast pit being used as a working shaft. The upcast pit (which is, in fact, the main gas and air-way, and which ought always to be closed from the external air, and the ascending air current guarded from disturbance or commotion, to prevent the slightest interruption to the current of air upon which the lives of all depend) is kept in a state of constant agitation by the ascent and descent of the "skips," loaded with coal, which nearly fill the shaft. To crown this, when every skip arrives at the top of the shaft, a carriage, boarded over, called the "runner," is wheeled over the mouth of the pit whilst the coal is landed, and then withdrawn to allow the skip to descend. It is obvious that the air, which should never be disturbed, is thus constantly liable to be conflicting currents, more or less, sometimes upwards and sometimes downwards; and whenever the mouth of the shaft is covered by the runner, the air is in a state of partial stagnation. But it sometimes occurs that the chain or tackle, by which the skip is suspended, breaks during the ascent of the upcast shaft; the skip then drops down the shaft, drives the air before it with great velocity along the air-head, and forces the gas out of the cavities into the workings, down upon the candles of the workmen; and this the author has known to happen many times.

When the two pits are sunk down through the stratum of coal 30 ft. in thickness, a "gate-road" or horse-way is next driven in the bottom of the coal, from 8 to 9 ft. high, and about the same width, commencing from the bottom of the downcast pit.

At the same time, (or rather before, as it should always precede the gate-road) an air-head is driven about the middle of the coal, or 15 ft. high from the "floor" or bottom of the coal, commencing from the downcast pit. The gate-road and air-head are then driven in parallel lines, at the same level upon which they commence, for the distance of 100 to 500 yards, or more, according to the quantity of coal intended to be cleared by the pits.

A series of "spouts" or openings are driven upwards from the gate-road into the air-head, at intervals of 10 or 15 yards (as the coal may give out more or less gas) to carry off the gas, and produce a current of air for the workmen,—each spout being closed up when a new one is made in advance. The excavation of the whole thickness of the stratum of coal, 30 ft. thick, is then proceeded with, by opening right and left from the end of the gate-road, and excavating a "side of work," which forms a rectangular cavity, say about 90 yards long by 50 yards wide, or about an acre, the whole of the coal being taken away as far as practicable, excepting the pillars of coal (generally 10 yards square and 10 yards distant from each other), which are left to support the superincumbent strata.

The air descending the downcast pit, and travelling along the gate-road into the workings, ascends to the air-head, and, traversing that, ascends the upcast pit, carrying with it the gas and impure vapors, as far as such imperfect and interrupted means will effect, and delivering them into the open air.

By this plan we may contrive (where the system is adopted) to ventilate the mine, though imperfectly, until the lower 15 feet of the coal is excavated; but where the whole thickness of the coal above the air-head has been removed, by undergoing the coal from the bottom, and dropping it down in large masses, the upper portion of the cavity, being above the level of the air-head, forms a reservoir for gas, which gradually accumulates, and has no means of escape,—a reservoir of the capacity of some hundred thousand of cubic feet, which may be wholly or in part occupied by gas. An accidental change in the direction of the current of air would turn the course of the air along the air-head into this reservoir of gas, and from thence into the gate-road, and render an explosion very probable. After the coal is extracted, a solid wall or "rib" of coal, from 6 to 10 yards thick, which is commonly termed a "fire-rib," is left all round the chamber, separating it from the next workings; and the entrance from the gate-road is securely walled up, to exclude the air, and prevent spontaneous combustion, which would otherwise, in a short period, take place. When an explosion occurs, it is generally followed by a second, or more, as proportions of the gas become successively charged with the due proportions of air; and the liability to these terrible explosions will always remain in mines thus worked, till, by some efficient means, the gas can be allowed a continuous escape, and a current of air can be insured to move always in one direction, with sufficient power to overcome all extraneous disturbing forces, either of the wind or any atmospheric changes.

In *fig. 971*, the system adopted and carried into operation by the author is shown. One pit *a*, is sunk, instead of two; and in the side of the shaft a smaller shaft *b* is cut, to form an "air chimney," and is afterwards separated from the main shaft; this air chimney is circular, and may be made about 3 feet diameter inside, or more, as may be required. The air-chimney is bricked at the same time with the shaft,—the circular brickwork of each forming a partition of double thickness and secure strength, from the two arches abutting against each other.

971

972

The gate-road *c*, is driven from the shaft at the bottom of the coal, as in the ordinary plan; but the air-head *d* is driven from the air chimney within 2 feet of the top of the coal, or higher if practicable, and runs into the vertical air chimney. The gate-road and air-head are carried forward in a parallel direction to the extent of the work.

as before described in the ordinary system; and "spouts" or openings, *e*, are driven upwards, to connect them at about every 15 yards—every spout being bricked up close, in succession, when a fresh one is made in advance, so as to make the current of air traverse the whole extent of the gate-road before it rises up to the air-head and passes away to the air chimney. These spouts can only be driven perpendicularly upwards from the gate-road to the air-head; and each of them being about 18 feet long in the 30 feet coal, a formidable practical difficulty was experienced by the author in the King Swinford pits, where the coal being contiguous to a great vault, it abounded in gas to so great a degree that when a spout was carried up a very few feet, it became so filled with gas that no man could work in it. But this difficulty was overcome by boring upwards from the spout a hole, 4 inches in diameter, into the air-head; the gas then passed off instantly, followed by a stream of air sufficient to ventilate the gate-road, and to enable the men to work with candles in the spout with perfect safety.

The excavation of the coal is commenced in the same manner as in the ordinary system, by driving at right angles from the end of the gate-road, to begin a "side of work;" and the ventilation is carried on completely and continuously from the extremity of the working, whilst the whole of the coal to the top is removed. The whole of the gas is constantly drained off from the upper surface of the coal by the air-head, and the numerous spouts or cross drains, which remain all open to the air-head, by means of a small pipe-hole left in the stopping as they are successively stopped, and which constantly drain off the gas most effectually, by piercing through and cutting the horizontal layers of coal, and thus tapping the several strata at so many different points. By this system the danger of any accumulation of gas in the cavities of the upper part of the workings is effectually prevented.

In the ordinary system of ventilation, it is manifest that only a very slight determining power compels the air to travel constantly in the same direction. Its current is, at all times, weak and insufficient, and liable to be deranged by the action of the wind, or atmospheric changes; and it is under no command whatever. To ensure safety, a constant current of air is indispensably necessary; it should be a current, too, maintained by natural causes, as far as possible, and never interrupted, for the reasons already assigned; and should be one that would not vary or fail.

To effect this, the ascending column of air must be rendered specifically lighter than the air of the descending column, which circulates through the workings; and this difference of specific gravity must be maintained constantly free from disturbance, by accidental causes, and, to such an extent, as to produce, under all circumstances, a total amount of propelling power that is found sufficient for the complete ventilation of the mine. This is accomplished by conducting the whole of the gas in a continuous ascending column, free from interruption or disturbance, up the separate air-chimney; and this ascending power is further increased by erecting a ventilating chimney (shown by dots, in the vertical section), of a sufficient height, on the surface of the ground, into the base of which the air-chimney is continued so as to form one uninterrupted air flue, from the top of the ventilating chimney, down to the air-head in the seam of coal. By this means a long experience has shown that a constant draught is established and secured, with the occasional aids of a small furnace or steam jet, which is amply sufficient, in all ordinary cases, to defy wind and weather, and also to produce a current sufficiently strong, that it may be split, and such portions withdrawn from the main stream of air as may be found requisite to carry on the preparatory work to maintain the get of coal.

The air in the gate-road and workings is warmed above the temperature of the air on the surface, in ordinary mean temperatures, by the heat of the earth, and is consequently rarefied; this is aided much more than would be generally supposed, by the heat proceeding from the numerous workmen, horses, and candles, employed in the mine; and the current is further increased by the escape of the gases, which are specifically lighter than the air,—the air-head forming, with the air-chimney, an uninterrupted and continuous passage from the workings, and delivering the gas into the ventilating chimney; thus a draught is constantly maintained sufficient for all usual purposes. The weak power of draught that exists in the old system is materially diminished by the upward shaft being of a larger size than the air-head through which the downward current of air must pass. The ascending current, in consequence, is languid and slow; whereas, in the author's judgment, it should have considerable velocity; and much more important advantages arise from this cause than philosophers account for or will admit.

Cases may occur in which it is desirable, for temporary purposes, to increase the draught, either when the external air is at a very high temperature, or from other causes; and this is at once obtained by adding a furnace, or a steam jet, of any required power, to the ventilating chimney. By means of a fire in this furnace, any degree of rarefaction may be produced that is desired in the ventilating chimney; and it is recommended always to build one where the boiler chimney cannot be used, that it may be used if it is wanted. In such cases, the flue of the furnace should be carried up perpendicularly, for 30 or 40 feet, against the side of the ventilating chimney, before it is

opened into it. This precaution will render a deflagration of the gases, passing up the chimney, impossible, when the furnace is used.

The principle of ventilating pits by an air-chimney used for no other purpose than the passage of the gas and the current of air from the workings to the surface, has been adopted by the author, in a more or less perfect form, for more than 30 years, in working the thick and thin mines, and has been found to give a complete and absolute command over the ventilation of every part of the mines. It is only, however, within the last few years, that he has had an opportunity of carrying it through many extensive pits systematically. In the whole of the author's mines, this system of ventilation is now completely carried on. The thick coal is sometimes worked in one pit, and in another pit, brooch coal, heathen coal, or the white iron stone lying beneath the coal; and sometimes the thick coal is worked in both. Very little preparation is necessary for this change from one to the other, as the air-chimney reaches to the lowest vein; and, a stopping being put in at the level of the vein intended to be got, a supply of air may be immediately procured at any required level. The thick coal abounded in gas in these pits; but it is now so drained, that all difficulties have disappeared. The use of the safety lamp has become a form rather than an essential.

A great improvement is perceptible in the health and comfort of the workmen employed. The air in these pits is always free from gas, and is 10° Fahr. cooler than the neighboring pits, worked on the ordinary system, owing to the regular supply of fresh air. They have been frequently tried, and found to be 62° or 64° in the workings; whilst, at the same time, the air in the working of pits ventilated in the ordinary way was found, in many cases, to be 72° to 74° : the former, the temperature of a comfortable sitting room, and the latter, that of a heated cotton-mill.

A great saving of expense from this system will be found also, not only in working the thick coal, but, subsequently, in getting the thinner veins of coal and ironstone. A considerable amount of outlay, as well as frequently a great loss of time, is incurred in obtaining the necessary supplies of air for working the successive strata of a mine. Whereas, the air-chimney is accessible at any point in the shaft; and the shaft is always kept well aired, which is of importance, as it is always found convenient to suspend the workings of the pit for a considerable time after the partial exhaustion of one of the strata, and before it may be desirable to commence the working of another.

It may be observed here, that an air-chimney may be very easily cut down any shaft that has been sunk in the usual way. The author has cut one down a shaft during the night whilst the pit continued to draw coal during the day. He executed one in a pit 140 yards deep, in about a month,—the pit continuing to draw coal during the day, whilst the air-chimney was made during the night.

Where large quantities of coal are to be drawn, a number of shafts are necessary. Two of these may be sunk at the usual distance 10 or 12 yards, near enough to be commanded by the same winding engine, but the shafts having no communication with each other. But if the form of the mine makes it more convenient, they may be sunk singly in any required situation; because each separate shaft will provide its own air, and each shaft will "get" the separate section of mine appropriated to it. By this means, small detached portions of mine have been got to advantage, that would not have paid for the expense of two shafts.

By this arrangement, a smaller quantity of air-heading is required to "get" the same area of coal; and the process of complete ventilation can be more easily carried out, as will be hereafter noticed; and, as communications between different shafts, by the gate-roads, might be occasionally convenient, these communications may be under the care and sole control of the mine director, who may keep the doors locked, if advisable: the ventilation is thus not materially disturbed.

In the different plans for ventilating mines, the merit appears to have been awarded to those more especially who have succeeded in forcing by any means, either mechanical, or by the use of powerful furnaces, the largest possible quantity of air through the workings in a given time. The principle explained in the present paper is totally different, and diametrically opposite; for it consists in draining the gas away from the coal before it is worked, and then getting the coal when it is thus drained, and carrying no more air through the mines than is required for light, life, and health.

Thus, to illustrate the difference between the two principles of ventilation, supposing that 1,000 cubic feet of gas per minute is emitted by the coal, and passed through the workings, 35,000 cubic feet of air per minute must, according to the old method, be passed through the mine,—that is 30,000 feet to dilute the gas, and 5000 feet to supply the workmen, horses, and candles, in the workings; but, if the whole of this 1000 feet of gas can be carried off by its own levity and intercepted from passing into the workings, then the mine will be better and more safely ventilated by 5000 feet of air per minute than by 25,000 feet in the former case; or, if the whole of the gas cannot be intercepted, then in such proportion as the volume of gas can be intercepted and carried away. And

supposing the opinion of the author to be correct, that the gas can be carried away without passing into the workings, and that therefore, a very greatly reduced quantity of air is necessary in the mine, it follows that (the gas being of the same specific gravity as atmospheric air, heated up to 512°) when the gas becomes diffused and united with the air, the volume of air and gas so united, is of less specific gravity than the air, and will maintain a natural ventilation of considerable power. It may be observed also, that very rapid currents of air through the passages of a mine are always attended with great inconvenience to the workman, and may be attended with great practical danger, from the circumstance, that the union or perfect admixture of the carbonated hydrogen with atmospheric air, though very rapid, is not instantaneous; and when in a mine not previously drained of its gas, large quantities of the gas suddenly escaping from powerful "blowers," are driven forwards by a current of air, moving from 7 to 10 feet per second, it is very conceivable that they are not diffused at once, but carried, in some degree, like a cloud of steam, forwards through the mine, till diffusion has brought a portion to the "firing point;" this, meeting with a light, or being driven, as is possible, through the wire of the safety lamp, will inevitably cause an explosion.

An objection that was made to the adoption of the system was, the possibility of some disturbance of the brickwork, which separated the air-chimney from the main shaft, either by a violent blow from the ascending skip (which, of course, could not be the case with the guides that are now generally used), or by any accidental explosion that might take place in the mine, which, it was contended, might force it outwards into the main shaft. A mere inspection of the plan must convince any practical person that such an occurrence is impossible. Any force from without would be resisted by the convex surface of the arch which encloses the small shaft, as any operating from within would be as effectually resisted by the convex surface of the main shaft. Not only did no such occurrence ever take place in the numerous pits where the plan has been used without guides; but even where the air chimney was cut square, possessing so much less resisting power, it remains now perfect and uninjured after a lapse of more than thirty years.

Another objection was, that the air-chimney was not of sufficient dimensions to ventilate the mine; and this objection was urged and re-urged in the face of the fact, that the author had expressly stated that cases might occur, where even a seven foot air-shaft might be required and employed to drain very fiery mines. The parties making this objection did not happen to recollect, that, in fact, this air-chimney was precisely of the same area as the air-head, which they themselves always employed, to form the communication between the workings and the upcast shaft. That, in fact, the air-chimney was nothing more nor less than a continuation of the air-head from the workings to the surface of the ground; and consequently, the effect of enlarging the air-chimney would be to diminish the velocity of the ascending column, and to lose the increased temperature the air had acquired in passing through the mine.

Another objection was, that in some of the thinner veins no upper air-head could be driven at a sufficient height to allow the gas to escape by its own levity, or to prevent it from getting admission to the workings. There may be exceptional cases; as, for example, if a mine can be supposed to lie upon a perfectly horizontal plane (but the author never saw an instance of a mine to any considerable extent answering this description; in all mines he has ever seen, the coal forms some angle to the horizon in some direction; and a very small angle will soon obtain a height of 6 or 7 feet, which is quite sufficient for the present purpose): in that case the air-head, communicating to the upcast shaft, may be made always to descend to the higher part of the plane, which will be quite sufficient to keep the mine clear from gas, by allowing it to pass off by its own levity. But, even if such a case ever should occur, a remedy may often be obtained, an instance of which has lately occurred to the author. A disturbance in the thick coal vein was found, breaking the coal through and throwing it into a trough 15 yards below its level: of course if the air-head had continued to follow the vein, it must have been depressed below its level to an extent equal to the whole thickness of the coal, which would have formed a barrier against the passage of the gas, like an inverted syphon, which the gas would not have passed. The remedy adopted by the author was, by commencing an air-head from the air-chimney in another measure, the "flying red," that lay 20 yards above the main coal, and continuing it till it had passed over the depressed point; a communication was then formed to the upper side of this depressed point, which at once established a rising air-head for the whole of the coal on the further side of the depression.

It may be perceived that the plan of ventilation here recommended is combined, in some measure, with the method of working the mines, and may be made more perfect and efficient by the adoption of a sound system. The common mode is that of working the mines in "panes," or "panels," leaving pillars or portions of coal to be extracted at a future period; but this is considered by the author as highly objectionable.

The danger of this method must be sufficiently obvious, when it is seen that the air

must be forced through the most crooked and winding channels, and compelled to pass along by artificial buildings, or "brattices," the accidental destruction or failure of which may suspend the whole ventilation.

But the plan exhibited will show that before any coal is got from the mine, in the method recommended by the author, the roads are carried out to the extreme extent that the coal is proposed to be worked, accompanied by their air-heads: by this means the complete drainage of the gas from the mass of coal proposed to be worked is effected; and these roads and their air-heads are originally made at infinitely less expense, and are always in a safe and secure state, as the excavations commence at the outside of the coal thus intended to be got; and no brattices are necessary, as double doors may be used in any of these roads down which the air is intended to circulate, either to regulate the quantity, or prevent its passage; and the current of air may be always brought to act directly upon the working face of the coal.

It may be objected, that these pillars must be left for a support, owing to the nature of the roof of the mine; but this the author has never yet seen, and is disposed to think it never can happen. He is getting veins of coal of 30 feet in thickness (in two successive workings of 15 feet each), also veins of 6 feet, 4 feet and 3 feet thicknesses. The roofs of these various coals differ in their tenacity, and some of them are extremely tender, and yet the whole of the coal is extracted from these veins, both the thickest and the thinnest, both large and small coal, with the greatest facility and safety.

The dangers obviated by this mode of working are doubly important; the roof gradually descends as the mine is excavated; all dangers are left behind; and the roof is consolidated into a compact mass by the weight of the superincumbent strata; consequently no "gouf" or hollow is ever formed, and no lodgment of gas can take place. Secondly, no large or small coal being left behind, the heating of the gouf, or the spontaneous combustion to which all mines are liable where small coal or slack is left, can never take place.

In working mines in panes and pillars (where a part of the coal is left and eventually lost, the difficulty of obtaining safe ventilation will be understood from the following remarks. At Newcastle-on-Tyne, the brattices have been all blown down by an explosion, and the workings filled with carbonic acid gas, and no means existing of quickly restoring the ventilation (as at the Felling Colliery), the pits and workings could not be entered, nor the bodies of the men recovered, for weeks, nay, even months. Every man in the mine, though out of the reach of the explosion, necessarily lost his life by the after-damp. A very recent case in Scotland, at Nitshill, where 69 lives were lost, is a striking example; although this pit had a good and distinct upcast shaft, the brattices were destroyed, the air of course proceeded along the shortest and most direct road from the downcast to the upcast shaft, and all the men who had been supplied with air by the diversion of the currents, depending entirely upon brattices (which were destroyed by the explosion), miserably perished, and the whole of the bodies could not be recovered in a week's time.

Where shafts are used of large diameter, divided by brattices, and of such large dimensions as to allow one side of the brattice to form the downcast and the other the upcast shaft, a similar result follows in the event of an explosion, to that last mentioned. A part of the brattice (probably at a considerable depth) is ruptured, and no current of air can be procured to admit of its repair, except by means which involve loss of much time and expense. In the meantime all those who may have been in the pit, at the time of the explosion, cannot be approached. The author presumes that some idea of economy introduced this system; but he is satisfied that upon this point an erroneous impression has prevailed. The expense of sinking these single divided shafts (of the usual diameter of 15 or 16 feet), is so very great, that it has led to the practice of working very extensive areas of coal by means of a single shaft; and this practice has further led to the different scientific contrivances for impelling the air over these immense areas, by which the ventilation of the works is rendered so much more difficult and uncertain.

Taking, for example, a pit of this description, of 15 feet diameter, by which is worked an area of 200 acres (and instances might be adduced where four, five, and six times that quantity has been thus worked), it is evident that the ventilation of a coal mine of this description, where the air passages have been extended to the length of 70 miles, must be attended with very great danger and vast expense.

Now, the author states as his opinion, and thinks he should have no difficulty in proving it correct, that four shafts might have been sunk on this area of 200 acres, 7½ feet diameter each, in proper positions with their air chimneys, for considerably less money than the one shaft cost; and if this can be established, it follows that the 200 acres being divided into sections of 50 acres each, the expense of the underground work would have been most materially diminished, and that the ventilation might have been effected with much greater ease and security in separate sections of 50 acres each, and the power of raising coal doubled, as there would be always two ascending and two descending curves, instead of one.

To sum up the conditions and principles requisite in carrying out the author's plan effectually, it may be stated :—

1st. That the air-head should always open into the highest practicable part of the mines.

2d. The air-head (or what may be properly called the gas-head), by which is meant, the horizontal air or gas-passage, shall always be in continuous communication from the workings to a vertical air chimney, or separate shaft, of 3, 4, 5 or more feet diameter, whichever shall be required; but always of sufficient dimensions to carry off the gas and air from the workings.

3d. That the air-head, or gas-head, shall not, in any part of its course, be depressed below the level of its opening into the workings.

4th. That the air-chimney (of such dimensions as the mine requires), by which is meant the vertical air or gas passage, shall never be used for any other purpose than the passage of the current of the gas and air from the workings to the surface; and that it shall be closed from the external air, till it arrives at its point of exit.

5th. That the vertical air-chimney should be closed at the top, and separated from the shaft, and should then be connected to the ventilated chimney, or the chimney connected by a horizontal flue with the boiler, so that the current of air may not at any time be disturbed or interrupted.

6th. That the gate roads should always be driven to the extreme point to which the workings of the coal are intended to be extended;—that the coal may previously be drained of its gas before any coal is got out; by which means the gate or horse-roads, and the air or gas-head, may be made, and afterwards be maintained, at considerable less expense, in a safe and secure state, and the gases be gradually drained off, before it is necessary to get the coal.

The author in conclusion states, that the case may be considered as exceptional, rather than general, in which any insurmountable difficulty, in providing the remedy for accidental derangements of the coal strata will present itself, and render it necessary to interfere materially with the principles recommended for adoption.

MINIUM. (Eng. and Fr.; *Red lead*; *Mennige*, Germ.) This pigment is a peculiar oxyde of lead, consisting of two atoms of the protoxyde and one of the peroxyde; but, as found in commerce, it always contains a little extra protoxyde, or yellow massicot. It is prepared by calcining lead upon a reverberatory hearth with a slow fire, and frequent renewal of the surface with a rake, till it becomes an oxyde, taking care not to fuse it. The calcined mass is triturated into a fine powder in a paint mill, where it is elutriated with a stream of water, to carry off the finely levigated particles, and to deposit them afterwards in tanks. The powder thus obtained, being dried, is called massicot. It is converted into minium, by being put in quantities of about 50 pounds into iron trays, 1 foot square, and 4 or 5 inches deep. These are piled up upon the reverberatory hearth, and exposed during the night, for economy of fuel, to the residuary heat of the furnace, whereby the massicot absorbs more oxygen, and becomes partially red lead. This, after being stirred about, and subjected to a similar low calcining heat once and again, will be found to form a marketable red lead.

The best minium, however, called *orange mine*, is made by the slow calcination of good white lead (carbonate) in iron trays. If the lead contains either iron or copper, it affords a minium which cannot be employed with advantage in the manufacture of flint-glass, for pottery glazes, or for house-painting.

Dumas found several samples of red lead which he examined to consist of the chemical sesquioxycide and the protoxyde, in proportions varying from 50 of the former and 50 of the latter, to 95.3 of the former and 4.7 of the latter. The more oxygen gas it gives out when heated, the better it is, generally speaking. See **NAPLES YELLOW**.

MINT. (*Monnaie*, Fr.; *Münze*, Germ.) The chief use of gold and silver is to serve for the medium of exchange in the sale and purchase of commodities, a function for which they are pre-eminently fitted by their scarcity, by being unalterable by common agents, and condensing a great value in a small volume. It would be very inconvenient in general to barter objects of consumption against each other, because their carriage would be expensive, and their qualities, in many cases, easily injured by external agents, &c. Gold is exempt from spontaneous change, and little costly in conveyance. Mankind at a very early period recognised how much easier it was to exchange a certain weight of gold or silver for objects of commerce, than to barter these objects themselves; and thenceforth all agreed to pay for their purchases in bars or ingots of these precious metals. But as their intrinsic value depends upon their purity, it became necessary to stamp on these bars their standard quality and their weight.

The inconvenience of using ingots in general trade, on account of the difficulty of defining fractional values, has determined governments to coin pieces of money, that is, quantities of metal whose weight and standard were made known and guaranteed by the effigies of the prince. It is true, indeed, that kings have become frequently coiners

of base money, by altering the weight and purity of the pieces apparently guaranteed by their impress. By such reductions, modern coins represent less of the precious metal than they did long ago. The ordinance of 755, for the coining of *sous* in France, proves that there was then as much fine silver in a single *sous* as there is now in a piece of 5 francs. During the last two centuries, indeed, silver coins have been diminished two thirds in weight.

But since knowledge has become more generally diffused, it has been shown that these frauds are equally injurious to the prince and to public faith. A sovereign may, it is true, declare by a decree that a shilling-piece is to be held worth five; but let us consider the consequences of this decree. All the individuals who have rents or capital sums to receive will be ruined, by getting in metallic value only one fifth of what is due to them: for although the nominal value should be the same as what they are entitled to, the intrinsic value would be but a fifth of the former; so that when they go to purchase the necessities or comforts of life, the dealer who sells them will at once raise their price five-fold. Each article of merchandise would thus acquire a nominal price 5 times greater; and he who had received payment of a debt in that money could not with it procure more than one fifth of the goods he could have previously commanded. That fraudulent law would, therefore, favor the debtors at the expense of the creditors; and as the state is commonly a great debtor, especially when it has recourse to the depreciation of the currency, it is obvious, that however illicit the gain which it makes, it still does gain; and this is the reason why princes have so often tampered with the mint. But let us examine the other consequences of this decree.

If the sovereign is a debtor, he is also a creditor and consumer, and even the most considerable of any. The taxes which he imposes are paid him in this deteriorated money, returned to him at its nominal value; and the purveyors of his armies, his buildings, and his household, sell him their commodities only at the actual market price. We may infer from this simple development that the coin with which he pays for any object has the same intrinsic value as the object; and that the name given to the coin is of no consequence. The prince may call it a crown, a ducat, or a rix-dollar at his pleasure; and he may assign any value to it that his caprice may suggest, yet this will not affect its value; for this is fixed beyond his control by the general nature of things. The prince may, indeed, at the outset, have profited by defrauding his creditors, and by authorizing each debtor to imitate him, but he will soon lose whatever he may have gained; and he will thus learn to his cost that it was bad policy to sacrifice his character by giving an example of a fraud so truly unprofitable in the issue. Moreover, he will lose still as much in the following years, because his treasury will receive only one fifth part of the taxes, unless he has quintupled the imposts. It may be said, indeed, that he might do the one thing along with the other. But every one knows that this power is neither generally permitted to princes, nor, if it were, could it be safely exercised. Serious political crises would combine to endanger the stability of the government; which besides, as the main consumer in the nation, must lose always as much as it seems to gain.

It is therefore manifest, that the alteration of the standard and weight of the coinage is at once a crime and a ruinous action for the sovereign power to commit; and hence such disastrous measures have been long abandoned in all well-regulated states. A gold sovereign is intrinsically worth 20 shillings, minus the cost of coinage; for were it worth more, all our sovereign pieces would be exported or melted down, to obtain the difference of value, however trifling it might be; and were it worth less, it would be the source of loss similar to what the state occasions when it depreciates the coin.

To comprehend the true value of a coin, we must regard this piece as an article of merchandise, whose value depends, as that of every thing else, on its usefulness, the esteem in which it is held, and the demand for it in the market. Grain increases in value when there are few sellers and many buyers; gold and silver are in the same predicament. The value of these metals is much augmented, indeed, by the universal currency they obtain when struck into money; a value additional to what they possess as objects of the arts. This value of the precious metals changes with time and place, like that of every merchandise; their abundance, since the discovery of America, has greatly lowered their value; that is, with the same weight of metal, we cannot at the present day purchase the same quantity of corn, land, wool, &c. as formerly. In the countries where silver abounds, this metal has less value, or, in other terms, commodities are dearer. Hence the metal tends to resume its equilibrium in flowing into those places where it is rarer; which means, that the consumer prefers purchasing his commodities there, rather than in another place, if he can easily transport them to where they are dearer.

It was formerly believed that a country is rich when it has a great deal of gold and silver; but this popular illusion has passed away. Spain has never been poorer than since the discovery of America, because its national industry has been ruined, and the

capitals merely passed through its hands to spread over the rest of Europe, from which it was obliged to import every thing that its want of home manufactures made it necessary to procure from abroad. We may add to these the prodigalities of the court, which, supposing its wealth inexhaustible, tried to corrupt all the ministers of the other powers, in furtherance of the chimera of universal dominion. The richest state is that in which there is most industry, whereby the inhabitants may procure every thing indispensable to the conveniences and comforts of life. Gold as a useful metal, and a medium of exchange, is undoubtedly very precious, and an adequate quantity for these exchanges must be had; but as it is good for very little besides, nay, as an excess is even hurtful, it soon begins to fly of itself towards the places where it is more needed or less common.

With regard to the relative value of gold and silver, several details have already been given in our view of the mineral wealth of the globe. Three centuries ago, an ounce of gold was worth at London or Paris 10 ounces of silver; now it may be exchanged for 15 ounces and a half.

The *par* of two coins results from the comparison of their weight and standard fineness. Let us take for an example the conversion of English gold sovereigns worth 20 shillings or a pound sterling, in relation to the French louis of 20 francs. The standard of the sovereign gold is 0.917, fine gold being 1000; its weight is 125.256 gr. English, or 7.980855 grammes; by multiplying this weight into its standard, we have a product of 7.318444035; this is, in grammes, the quantity of pure gold contained in the sovereign piece. The piece of 20 francs has a legal standard of 0.9; and multiplying this number by the weight of the louis, 6.45161 grammes, we find that it contains 5.806449 of pure metal. We then make this proportion:—

As 5.806449 : 20 francs :: 7.31844 : 25.2079 francs; or the value of the English sovereign is nearly 25.21 francs, in French gold coin. A similar calculation may be made for silver coins. The French rule for finding the *par* of a foreign gold coin, or its intrinsic value in francs, is to multiply its weight by its standard or titre, and that product by $\frac{3}{8}$. The *par* of foreign silver money, or its intrinsic value in francs, is obtained by multiplying its weight in grammes by its standard in thousand parts, and by $\frac{2}{9}$. The French 5-franc piece has its standard or titre at 0.9, and weighs 25 grammes.

The assaying of gold for coin and trinkets requires very delicate management. The French take half a gramme at most (about $7\frac{1}{2}$ grains) of gold, and fuse it with thrice its weight of silver, as already described under ASSAY. The parting is the next operation. For this purpose the button of gold and silver alloy is first hammered flat on a piece of steel, and then made feebly red hot in burning charcoal or over a lamp flame. After being thus annealed, the metal is passed through the rolling press, till it be converted into a plate about $\frac{1}{10}$ of an inch thick. After annealing this riband, it is coiled into a spiral form, introduced immediately into a small matrass of a pear shape, an assay matrass, and about 500 grains of nitric acid, sp. grav. 1.185, are poured over it. Heat being now applied to the vessel, the solution of the silver and copper alloys ensues, and after 22 minutes of constant ebullition, the liquid is poured off and replaced by an equal quantity of nitric acid, likewise very pure, but of the density 1.28. This is made to boil for about 10 minutes, and is then poured off, when the matrass is filled up with distilled water to the brim. In conclusion, a small annealing crucible is inverted as a cup over the mouth of the matrass, which is now turned upside down with a steady hand; the slip of metal falls into the crucible through the water; which by sustaining a part of its weight softens its descent and prevents its tearing. The matrass is then dexterously removed, without letting its water overflow the crucible. The water is gently decanted from the crucible, which is next covered, placed in the middle of burning charcoal, and withdrawn whenever it becomes red hot. After cooling, the metal slip is weighed very exactly, whence the weight of fine gold in the alloy is known. Stronger acid than that prescribed above would be apt to tear the metallic riband to pieces, and it would be difficult to gather the fine particles of gold together again. The metallic plate becomes at last merely a golden sieve, with very little cohesion. When copper is to be separated from gold by cupellation, a higher temperature is requisite than in cupelling silver coin.

The coining apparatus of the Royal Mint of London is justly esteemed a masterpiece of mechanical skill and workmanship. It was erected in 1811, under the direction of the inventor, Mr. Boulton; and has since been kept in almost constant employment.

The melting pots (fig. 973) are made of cast-iron, and hold conveniently 400 pounds of metal. They are furnished with a spout or lip for pouring out the metal, and with two ears, on which the tongs of the crane lay hold in lifting them out of the furnace. The pot rests on pedestals on the grate of the furnace, and has a ring cast on its edge to prevent the fuel falling into it. Whenever it becomes red hot, the metal properly prepared and mixed, so as to produce an alloy containing 0.915 parts of gold, is put in, and during the melting, which occupies some hours, it is occasionally stirred. The moulds are meanwhile prepared by warming them in a stove, and thereafter by rubbing their

inside surfaces with a cloth dipped in oil, by which means the ingots cast in them get a better surface. Fig. 974 represents a side view of the carriage, charged with its

moulds. When the proper number of moulds is introduced, the screws at the end, represented at *t t*, are screwed fast, to fix them all tight.

The pot of fused metal is lifted out of the furnace *b*; the crane (fig. 975,) then

swung round, and lowered down into the cradle *l, m, n, o* of the pouring machine, until the ring on the edge of it rests on the iron hoop *n*, which, being screwed tight up, holds it secure, and the crane-tongs are removed. One of the assistants now takes the winch handle *s* in one hand, and *y* in the other. By turning *y* he moves the carriage forward, so as to bring the first mould beneath the lip of the melting pot; and by turning *s*, he inclines the pot, and pours the metal into the mould. He then fills the other moulds in succession. The first portion of liquid metal is received in a small iron spoon, and is reserved for the assay-master; a second sample is taken from the centre of the pot, and a third from the bottom part. Each of these is examined as to its quality.

The ingots, which are about 10 inches long, 7 broad, and 6 tenths of an inch thick, are now carried to the rolling mill,

Fig. 976, where *A* represents a large spur wheel, fixed on the extremity of a long

horizontal shaft *n*, extending beneath the whole mill. This wheel and shaft are driven by a smaller wheel, fixed on the main or fly-wheel shaft of a steam engine of 36-horse power. The main shaft *n* of the rolling mill has wheels *c*, *d*, *e* fixed upon it, to give motion to the respective rollers, which are mounted at *r* and *g*, in strong iron frames, bolted to the iron sills *u*, which extend through the whole length of the mill, and rest upon the masonry, in which the wheels are concealed. The two large wheels *c* and *e* give motion to the wheels *h*, *i*, which are supported on bearings between two standards *b*, *b*, bolted down to the ground sills. On the ends of the axes of these wheels are heads for the reception of coupling boxes *d*, *d*, which unite them to short connecting shafts *k*, *l*; and these again, by means of coupling boxes, convey motion to the upper rollers *e*, *e*, of each pair, at *r* and *g*. The middle wheel *p* upon the main shaft *n* gives motion to the lower rollers in a similar manner. Thus both the rollers *e*, *f* of each frame receive their motion from the main shaft with equal velocity, by means of wheels of large radius, which act with much more certainty than the small pinions usually employed in rolline mills to connect the upper and lower rollers, and cause them to move together.

The rolling mill contains four pairs of rollers, each driven by its train of wheel work; the mill, therefore, consists of two such sets of wheels and rollers as are represented in our figure. The two shafts are situated parallel to each other, and receive their motion from the same steam engine. This admirable rolling mill was erected by John Rennie, Esq.

The ingots are heated to redness in a furnace before they are rolled. The two furnaces for this purpose are situated before two pairs of rollers, which, from being used to consolidate the metal by rolling whilst hot, are termed breaking-down rollers. Two men are employed in this operation; one taking the metal from the furnace with a pair of tongs, introduces it between the rollers; and the other, catching it as it comes through, lifts it over the top roller, and returns it to his fellow, who puts it through

This machine is worked by a spur-wheel at the extremity of the main shaft *n* of the rolling mill (fig. 976.) It consists of a framing of iron *A*, supporting two shafts *n*, which are parallel to each other, and move together by means of two equal spur-wheels *c*, *c*, the lower one of which works with the teeth of the great wheel above mentioned, upon the main shaft of the rolling mill. At the extremities of the two shafts, wheels or circular cutters are fixed with their edges overlapping each other a little way. *r* represents a shelf on which the plate is laid, and advanced forward to present it to the cutter; and *g* is a ledge or guide, screwed down on it, to conduct the metal and to regulate the breadth of the piece to be cut off. Hence the screws which fasten down the ledge are fitted in oblong holes, which admit of adjustment. The workman holds the plate flat upon the surface *r*, and pushing it towards the shears, they will lay hold of it, and draw it through until they have cut the whole length. The divided parts are also prevented from curling up into scrolls, as they do when cut by a common pair of shears; because small shoulders on *e* and *b*, behind the cutting edge, keep them straight. Behind the standard, supporting the back pivots of the shafts *n* of the cutter, is a frame *l*, with a screw *m* tapped through it. This is used to draw the axis of the upper cutter *b* endwise, and keep its edge in close contact with the edge of the other cutter *e*. The slips or ribands of plate are now carried to the other two pairs of rollers in the rolling mill, which are made of case-hardened iron, and better polished than the breaking-down rollers. The plates are passed cold between these, to bring them to exactly the same thickness; whence they are called adjusting or planishing rollers. The workman here tries every piece by a common gauge, as it comes through. This is a piece of steel having a notch in it; the inside lines of which are very straight, and inclined to one another at a very acute angle. They are divided by fine lines, so that the edge of the plate being pressed into the notch, will have its thickness truly determined by the depth to which it enters, the divisions showing the thickness in fractions of an inch.

In rolling the plate the second time, all the plates are successively passed through the rollers; then the rollers being adjusted, they are passed through another time. This is repeated thrice or even four times; after which they are all tried by the gauge, and

thus sorted into as many parcels as there are different thicknesses. It is a curious circumstance, that though the rollers are no less than 14 inches in diameter, and their frame proportionally strong, they will yield in some degree, so as to reduce a thick plate in a less degree than a thin one; thus the plates which have all passed through the same rollers, may be of 3 or 4 different degrees of thickness, which being sorted by the gauge into as many parcels, are next reduced to the exact dimension, by adapting the rollers to each parcel. The first of the parcel which now comes through is tried, by cutting out a circular piece with a small hand machine, and weighing it. If it proves either too light or too heavy, the rollers are adjusted accordingly, till by a few such trials they are found to be correct, when all the parcel is rolled through. The trial plates which turn out to be too thin, are returned as waste to the melting-house. By these numerous precautions, the blanks or circular discs, when cut out by the next machine, will be very nearly of the same weight; which they would scarcely be, even if the gauge determined all the plates to the same thickness, because some being more condensed than others, they would weigh differently under the same volume.

A great improvement has been made on that mode of lamination, by the late Mr. Barton's machine for equalizing the thickness of slips of metal for making coin, which has been for several years introduced into the British mint. A side elevation is shown in *fig. 978*, and a plan in *fig. 979*. It operates in the same way as wire-drawing mechanisms; namely, pulls the slips of metal forcibly through an oblong opening, left between two surfaces of hardened steel. The box or case which contains the steel dies, composed of two hardened cylinders, is represented at *c* in *fig. 978*. The pincers employed to hold the metal, and draw it through, are shown at *s r*.

The slips of metal to be operated on by the drawing machine, are first rendered thinner at one end, that they may be introduced between the dies, and also between the jaws of the pincers. This thinning of the ends is effected by another machine, consisting of a small pair of rollers, mounted in an iron frame, similar to a rolling-mill. The upper roller is cylindrical, but the lower is formed with 3 flat sides, leaving merely portions of the cylinder entire, between these flat sides. The distance between the centres of the rollers is regulated by screws, furnished with wheels on their upper ends, similar to what is seen in the drawing dies at *c*. The two rollers have pinions on their axes, which make them revolve together; they are set in motion by an endless strap passing round a drum, upon whose axis is a pinion working into the teeth of a wheel fixed upon the axis of the lower roller.

The end of a slip of metal is presented between the rollers while they are in motion, not on that side of the roller which would operate to draw in the slip between them, as in the rolling-press above described, but on the contrary side, so that when one of the flat sides of the under roller fronts horizontally the circumference of the upper roller, an opening is formed, through which the slip of metal is to be inserted until it bears against a fixed stop at the back of the rollers. As the rollers continue to turn round, the cylindrical portions come opposite to each other, and press the metal between them, forcing it outwards, and rendering the part which has been introduced between the rollers as thin as the space between their cylindrical surfaces. Thus the end of the slip of metal becomes attenuated enough to pass between the dies of the drawing machine, and to be seized by the pincers.

In using the drawing machine, a boy takes hold of the handle *s* of the pincers, their hook of connexion with the endless chain *l*, *l*, not shown in the present figure, being disengaged, and he moves them upon their wheels towards the die-box *c*. In this movement the jaws of the pincers get opened, and they are pushed up so close to the

die-box that their jaws enter a hollow, which brings them near the dies, enabling them to seize the end of the slip of metal introduced between them by the action of the preparatory rollers. The boy now holds the handle *s* on the top of the pincers fast, and with his other hand draws the handle *x* backwards. Thus the jaws are closed, and the metal firmly gripped. He now presses down the handle *x* till a hook on the under side of the pincers seizes the endless chain as it moves along, when it carries the pincers, and their slip of metal, onwards with it. Whenever the whole length of the metallic riband has passed through between the dies, the strain on the pincers is suddenly relieved, which causes the weight *r* to raise their hook out of the chain, and stop their motion. The machine in the mint has two sets of dies, and two endless chains, as represented in the plan, fig. 979. *N N*, are toothed wheels in the upper end of the die-box, furnished with pinions and levers, for turning them round, and adjusting the distance between the dies. A large spur-wheel *G*, is fixed upon the axis *r*, to give motion to the endless chains; see both figures. This spur-wheel is turned by a pinion *H*, fixed upon an axis *m*, extending across the top of the frame, and working in bearings at each end. A spur-wheel *i*, is fixed upon the axis *m*, and works into the teeth of a pinion *k*, upon a second axis across the frame, which carries likewise a drum wheel *L*, through which motion is communicated to the whole mechanism by an endless strap.

The cutting-out machine is exhibited in fig. 980. *A A* is a basement of stone to support

an iron plate *B B*, on which stand the columns *C C*, that bear the upper part *D* of the frame. The iron frame of the machine *E, F, G*, is fixed down upon the iron plate *B, B*. The punch *d* is fixed in the lower part of the inner frame, and is moved up and down by the screw *a*, which is worked by wipers turned by a steam engine, impelling the lever *H*, and turning backwards and forwards the axis *G*, through a sufficient space for cutting the thickness of the metallic lamina. A boy manages this machine. There are twelve of them mounted on the same basement frame in a circular range contained in an elegant room, lighted from the roof. The whole are moved by a steam engine of 16 horse power.

The blanks or *planchets* thus cut out, were formerly adjusted by filing the edges, to bring them to the exact weight; a step which Mr. Barton's ingenious mechanics has rendered in a great measure unnecessary. The edge is then milled, by a process which Mr. Boulton desires to keep secret, and which is therefore not shown in our mint.

But the French mint employs a very elegant machine for the purpose of lettering or milling the edges, called the *cordons des monnaies*, invented by M. Gengembre, which has entirely superseded the older milling machine of M. Castaing, described in the Encyclopedias. The Napoleon coins of France bear on the edge, in sunk letters, the legend, *Dieu protège la France*; and those of the king, *Domine salvum fac regem*. This is marked before striking the blank or *flan*. One machine imprints this legend, and its service is so prompt and easy, that a single man marks in a day 20,000 pieces of 5 francs, or 100,000 francs.

Each of the two arc dies *E, D*, (fig. 981,) carries one half of the legend, engraved in relief on the curved face; these arcs are pieces of steel tempered very hard, and fixed with two screws, one immovably at *E*, on the sill which bears the apparatus; the other at *D*, at the extremity of the lever *F, D*, which turns round the axis *C*. The letters of these dies are exactly parallel, and inscribed in an inverse order on the dies. An alternating circular motion is communicated to the handle *P*. The curvatures of the two dies are arcs of circles described from the centre *C*; and the interval which separates them, or the difference of the radii, is precisely the diameter of the piece to be milled.

As the centre *C* sustains the whole strain of the milling, and produces, of consequence, a hard friction, this axis must possess a considerable size. It is composed of a square

truncated cone of tempered steel, which enters into an eye of the moveable piece *r*, *d*. This cone is kept on the plate of the metal *n*, which bears the whole machine, by a nut, whose screw, by being tightened or slackened, gives as much freedom as is requisite for the movement of rotation, or removes the shake which hard service gives to the cone in its eye. The middle thickness of the hole of the moveable piece *r*, *d*, and the axis of the lever *r*, which terminates it, are exactly on a level with the engraved letters of the die, so that no strain can derange the moveable piece, or disturb the centre by its oscillations.

At *a* is a vertical tube, containing a pile of blanks for milling. It is kept constantly full; the tube being open at both ends, a little elevated above the circular space *a*, *κ*, *b*, which separates the dies, and fixed by a tail *m* with a screw to the motionless piece *λ*, *α*. The branch *ι*, *c*, moveable with the piece *r*, *d*, passes under the tube, and pushes before it the blank at the bottom of the column, which is received into a small excavation in the form of a circular step, and carried forwards. Matters are thus so arranged as to regulate the issue of the blanks, one by one, on the small step, called the *posoir* (bed.)

As soon as the blank is pushed forwards into contact with the lower edge of the engraved grooves, it is seized by them, and carried on by the strain of milling, without exposing the upper or under surfaces of the blank to any action which may obstruct the printing on its edge.

The blank is observed to revolve between the two dies according as the lever *r* completes its course, and this blank passing from *a* to *κ*, then to *b*, meets a circular aperture *δ*, through which it falls into a drawer placed under the sill.

The range of the moveable lever *r* is regulated by four pieces, *r*, *r*, *r*, *r*, solidly sunk in the plate *n*, *κ*, which bears the whole apparatus. A stud placed on this lever towards *d*, makes the arm of the *posoir* *ι* *c* retire no farther than is necessary for the little blank to issue from the column; and a spring fixed to the centre *c*, and supported on a peg, brings back the *posoir*; so that when a screw *ι* comes to strike against the column, the *posoir* stops, and the moveable die *d*, which continues its progress, finds the blank in a fit position for pressing, seizing, and carrying it on, by reaction of the fixed die *κ*. Thus the edge of the blank is lettered in half a second. A hundred may easily be marked in about three minutes.

The coining press is the most beautiful part of the whole mechanism in the British mint; but the limits of this volume will not allow of its being figured upon an adequate scale. An engraving of it may be seen in the Encyclopedia Britannica.

The only attention which this noble machine requires is that of a little boy, who stands in a sunk place before the press, and always keeps the tube full of blanks. He has two strings, one of which, when pulled, will put the press in motion by the concealed mechanism in the apartment above; and the other string, when snatched, stops the press. This coining operation goes on at the rate of 60 or 70 strokes per minute; and with very few interruptions during the whole day. The press-room at the Royal Mint contains eight machines, all supported on the same stone base; and the iron beams between the columns serve equally for the presses on each side. The whole has therefore a magnificent appearance. The eight presses will strike more than 19,000 coins in an hour, with only a child to supply each. The grand improvement in these presses consists; 1. in the precision with which they operate to strike every coin with equal force, which could not be ensured by the old press impelled by manual labor; 2. The rising collar or steel ring in which they are struck, keeps them all of one size, and makes a fair edge, which was not the case with the old coins, as they were often rounded and defaced by the expansion of the metal under the blow; 3. The twisting motion of the upper die is thought to produce a better surface on the flat parts of the coin; but this is somewhat doubtful; 4. The feeding mechanism is very complete, and enables the machine to work much quicker than the old press did, where the workman, being in constant danger of having his fingers caught, was obliged to proceed cautiously, as well as to place the coin true on the die, which was seldom perfectly done. The feeding mechanism of the above press is a French invention; but Mr. Boulton is supposed to have improved upon it.

MIRRORS. See COPPER and GLASS.

MISPICKEL is arsenical pyrites.

MOHAIR is the hair of a goat which inhabits the mountains in the vicinity of Angora, or Asia Minor.

MOIRE'E METALLIQUE, called in this country crystallized tin-plate, is a variegated primrose appearance, produced upon the surface of tin-plate, by applying to it in a heated state some dilute nitro-muriatic acid for a few seconds, then washing it with water, drying, and coating it with lacker. The figures are more or less beautiful and diversified, according to the degree of heat, and relative dilution of the acid. This mode of ornamenting tin-plate is much less in vogue now than it was a few years ago.

MOLASSE is a sandstone belonging to the tertiary strata, employed under that name by the Swiss for building.

MOLASSES is the brown viscid uncrystallizable liquor, which drains from cane sugar in the colonies. See **SUGAR**.

MOLYBDENUM (*Molybdène*, Fr.; *Molybden*, Germ.) is a rare metal which occurs in nature sometimes as a sulphuret, sometimes as molybdic acid, and at others as molybdate of lead. Its reduction from the acid state by charcoal requires a very high heat, and affords not very satisfactory results. When reduced by passing hydrogen over the ignited acid, it appears as an ash-gray powder, susceptible of acquiring metallic lustre by being rubbed with a steel burnisher; when reduced and fused with charcoal, it possesses a silver white color, is very brilliant, hard, brittle, of specific gravity 8.6; it melts in a powerful air-furnace, oxydizes with heat and air, burns at an intense heat into molybdic acid, dissolves in neither dilute sulphuric, muriatic, nor fluoric acids, but in the concentrated sulphuric and nitric.

The protoxyde consists of 85.69 of metal, and 14.31 of oxygen; the deutoxyde consists of 75 of metal, and 25 of oxygen; and the peroxyde, or molybdic acid, of 66.6 of metal, and 33.4 of oxygen. These substances are too rare at present to be used in any manufacture.

MORDANT, in dyeing and calico-printing, denotes a body which, having a twofold attraction for organic fibres and coloring particles, serves as a bond of union between them, and thus gives fixity to dyes; or it signifies a substance which, by combining with coloring particles in the pores of textile filaments, renders them insoluble in hot soapy and weak alkaline solutions. In order properly to appreciate the utility and the true functions of mordants, we must bear in mind that coloring matters are peculiar compounds possessed of certain affinities, their distinctive characters being not to be either acid or alkaline, and yet to be capable of combining with many bodies, and especially with salifiable bases, and of receiving from each of them modifications in their color, solubility, and alterability. Organic coloring substances, when pure, have a very energetic attraction for certain bodies, feeble for others, and none at all for some. Among these immediate products of animal or vegetable life, some are soluble in pure water, and others become so only through peculiar agents. We may thus readily conceive, that whenever a dye-stuff possesses a certain affinity for the organic fibre, it will be able to become fixed on it, or to dye it without the intervention of mordants, if it be insoluble by itself in water, which, in fact, is the case with the coloring matters of safflower, annatto, and indigo. The first two are soluble in alkalis; hence, in order to use them, they need only be dissolved in a weak alkaline ley, be thus applied to the stuffs, and then have their tinctorial substance precipitated within their pores, by abstracting their solvent alkali with an acid. The coloring matter, at the instant of ceasing to be liquid, is in an extremely divided state, and is in contact with the organic fibres for which it has a certain affinity. It therefore unites with them, and, being naturally insoluble in water, that is, having no affinity for this vehicle, the subsequent washings have no effect upon the dye. The same thing may be said of indigo, although its solubility in the dye-bath does not depend upon a similar cause, but is due to a modification of its constituent elements, in consequence of which it becomes soluble in alkalis. Stuffs plunged into this indigo bath get impregnated with the solution, so that when again exposed to the air, the dyeing substance resumes at once its primitive color and insolubility, and washing can carry off only the portions in excess above the intimate combination, or which are merely deposited upon the surface of the stuff.

Such is the result with insoluble coloring matters; but for those which are soluble it should be quite the reverse, since they do not possess an affinity for the organic fibres, which can counterbalance their affinity for water. In such circumstances, the dyer must have recourse to intermediate bodies, which add their affinity for the coloring matter to that possessed by the particles of the stuff, and increase by this twofold action the intimacy and the stability of the combination. These intermediate bodies are the true mordants.

Mordants are in general found among the metallic bases or oxydes; whence they might be supposed to be very numerous, like the metals; but as they must unite the twofold condition of possessing a strong affinity for both the coloring matter and the organic fibre, and as the insoluble bases are almost the only ones fit to form insoluble combinations, we may thus perceive that their number may be very limited. It is well known, that although lime and magnesia, for example, have a considerable affinity for coloring particles, and form insoluble compounds with them, yet they cannot be employed as mordants, because they possess no affinity for the textile fibres.

Experience has proved, that of all the bases, those which succeed best as mordants are alumina, tin, and oxyde of iron; the first two of which, being naturally white, are the only ones which can be employed for preserving to the color its original tint, at least

without much variation. But whenever the mordant is itself colored, it will cause the dye to take a compound color quite different from its own. If, as is usually said, the mordant enters into a real chemical union with the stuff to be dyed, the application of the mordant should obviously be made in such circumstances as are known to be most favorable to the combination taking place; and this is the principle of every day's practice in the dye-house.

In order that a combination may result between two bodies, they must not only be in contact, but they must be reduced to their ultimate molecules. The mordants that are to be united with stuffs are, as we have seen, insoluble of themselves, for which reason their particles must be divided by solution in an appropriate vehicle. Now this solvent or menstruum will exert in its own favor an affinity for the mordant, which will prove to that extent an obstacle to its attraction for the stuff. Hence we must select such solvents as have a weaker affinity for the mordants than the mordants have for the stuffs. Of all the acids which can be employed to dissolve alumina, for example, vinegar is the one which will retain it with least energy, for which reason the acetate of alumina is now generally substituted for alum, because the acetic acid gives up the alumina with such readiness, that mere elevation of temperature is sufficient to effect the separation of these two substances. Before this substitution of the acetate, alum alone was employed; but without knowing the true reason, all the French dyers preferred the alum of Rome, simply regarding it to be the purest; it is only within these few years that they have understood the real grounds of this preference. This alum has not, in fact, the same composition as the alums of France, England, and Germany, but it consists chiefly of cubic alum having a larger proportion of base. Now this extra portion of base is held by the sulphuric acid more feebly than the rest, and hence is more readily detached in the form of a mordant. Nay, when a solution of cubic alum is heated, this redundant alumina falls down in the state of a subsulphate, long before it reaches the boiling point. This difference had not, however, been recognised, because Roman alum, being usually soiled with ochre on the surface, gives a turbid solution, whereby the precipitate of subsulphate of alumina escaped observation. When the liquid was filtered, and crystallized afresh, common octahedral alum alone was obtained; whence it was most erroneously concluded, that the preference given to Roman alum was unjustifiable, and that its only superiority was in being freer from iron.

Here a remarkable anecdote illustrates the necessity of extreme caution, before we venture to condemn from theory a practice found to be useful in the arts, or set about changing it. When the French were masters in Rome, one of their ablest chemists was sent thither to inspect the different manufactures, and to place them upon a level with the state of chemical knowledge. One of the fabrics, which seemed to him furthest behindhand, was precisely that of alum, and he was particularly hostile to the construction of the furnaces, in which vast boilers received heat merely at their bottoms, and could not be made to boil. He strenuously advised them to be new modelled upon a plan of his own; but, notwithstanding his advice, which was no doubt very scientific, the old routine kept its ground, supported by utility and reputation, and very fortunately, too, for the manufacture; for had the higher heat been given to the boilers, no more genuine cubical alum would have been made, since it is decomposed at a temperature of about 120° F., and common octahedral alum would alone have been produced. The addition of a little alkali to common alum brings it into the same basic state as the alum of Rome.

The two principal conditions, namely, extreme tenuity of particles, and liberty of action, being found in a mordant, its operation is certain. But as the combination to be effected is merely the result of a play of affinity between the solvent and the stuff to be dyed, a sort of partition must take place, proportioned to the mass of the solvent, as well as to its attractive force. Hence the stuff will retain more of the mordant when its solution is more concentrated, that is, when the base diffused through it is not so much protected by a large mass of menstruum; a fact applied to very valuable uses by the practical man. On impregnating in calico printing, for example, different spots of the same web with the same mordant in different degrees of concentration, there is obtained in the dye-bath a depth of color upon these spots intense in proportion to the strength of their various mordants. Thus, with solution of acetate of alumina in different grades of density, and with madder, every shade can be produced, from the fullest red to the lightest pink; and, with acetate of iron and madder, every shade from black to pale violet.

We hereby perceive that recourse must indispensably be had to mordants at different stages of concentration; a circumstance readily realized by varying the proportions of the watery vehicle. See CALICO-PRINTING and MADDER. When these mordants are to be topically applied, to produce partial dyes upon cloth, they must be thickened with starch or gum, to prevent their spreading, and to permit a sufficient body of them to become attached to the stuff. Starch answers best for the more neutral mordants, and

gum for the acidulous; but so much of them should never be used, as to impede the attraction of the mordant for the cloth. Nor should the thickened mordants be of too desiccative a nature, lest they become hard, and imprison the chemical agent before it has had an opportunity of combining with the cloth, during the slow evaporation of its water and acid. Hence the mordanted goods, in such a case, should be hung up to dry in a gradual manner, and when oxygen is necessary to the fixation of the base, they should be largely exposed to the atmosphere. The foreman of the factory ought, therefore, to be thoroughly conversant with all the minutiae of chemical reaction. In cold and damp weather he must raise the temperature of his drying-house, in order to command a more decided evaporation; and when the atmosphere is unusually dry and warm, he should add deliquescent correctives to his thickening, as I have particularized in treating of some styles of calico-printing. But, supposing the application of the mordant and its desiccation to have been properly managed, the operation is by no means complete; nay, what remains to be done is not the least important to success, nor the least delicate of execution. Let us bear in mind that the mordant is intended to combine not only with the organic fibre, but afterwards also with the coloring matter, and that, consequently, it must be laid entirely bare, or scraped clean, so to speak, that is, completely disengaged from all foreign substances which might invest it, and obstruct its intimate contact with the coloring matters. This is the principle and the object of two operations, to which the names of *dunging* and *clearing* have been given.

If the mordant applied to the surface of the cloth were completely decomposed, and the whole of its base brought into chemical union with it, a mere rinsing or scouring in water would suffice for removing the viscid substances added to it, but this never happens, whatsoever precautions may be taken; one portion of the mordant remains untouched, and besides, one part of the base of the portion decomposed does not enter into combination with the stuff, but continues loose and superfluous. All these particles, therefore, must be removed without causing any injury to the dyes. If in this predicament the stuff were merely immersed in water, the free portion of the mordant would dissolve, and would combine indiscriminately with all the parts of the cloth not mordanted, and which should be carefully protected from such combination, as well as the action of the dye. We must therefore add to the scouring water some substance that is capable of seizing the mordant as soon as it is separated from the cloth, and of forming with it an insoluble compound; by which means we shall withdraw it from the sphere of action, and prevent its affecting the rest of the stuff, or interfering with the other dyes. This result is obtained by the addition of cow-dung to the scouring bath; a substance which contains a sufficiently great proportion of soluble animal matters, and of coloring particles, for absorbing the aluminous and ferruginous salts. The heat given to the dung-bath accelerates this combination, and determines an insoluble and perfectly inert coagulum.

Thus the dung-bath produces at once the solution of the thickening paste; a more intimate union between the alumina or iron and the stuff, in proportion to its elevation of temperature, which promotes that union; an effectual subtraction of the undecomposed and superfluous part of the mordant, and perhaps a commencement of mechanical separation of the particles of alumina, which are merely dispersed among the fibres; a separation, however, which can be completed only by the proper scouring, which is done by the dash-wheel with such agitation and pressure (see BLEACHING and DUNGING) as vastly facilitate the expulsion of foreign particles. See also BRAN.

Before concluding this article, we may say a word or two about astringents, and especially gall-nuts, which have been ranked by some writers among mordants. It is rather difficult to account for the part which they play. Of course we do not allude to their operation in the black dye, where they give the well known purple-black color with salts of iron; but to the circumstance of their employment for madder dyes, and especially the Adrianople red. All that seems to be clearly established is, that the astringent principle or tannin, whose peculiar nature in this respect is unknown, combines like mordants with the stuffs and the coloring substance, so as to fix it; but as this tannin has itself a brown tint, it will not suit for white grounds, though it answers quite well for pink grounds. When white spots are desired upon a cloth prepared with oil and galls, they are produced by an oxygenous discharge, effected either through chlorine or chromic acid.

MORDANT is also the name sometimes given to the adhesive matter by which gold-leaf is made to adhere to surfaces of wood and metal in gilding. Paper, vellum, taffety, &c., are easily gilt by the aid of different mordants, such as the following: 1. beer in which some honey and gum arabic have been dissolved; 2. gum arabic, sugar and water; 3. the viscid juice of onion or hyacinth, strengthened with a little gum arabic. When too much gum is employed, the silver or gold leaf is apt to crack in the drying of the mordant. A little carmine should be mixed with the above colorless

liquids, to mark the places where they are applied. The foil is applied by means of a dossil of cotton wool, and when the mordant has become hard, the foil is polished with the same.

The best medium for sticking gold and silver leaf to wood is the following, called *miz-tion* by the French artists:—1 pound of amber is to be fused, with 4 ounces of mastic in tears, and 1 ounce of Jewish pitch, and the whole dissolved in 1 pound of linseed oil rendered drying by litharge.

Painters in distemper sometimes increase the effect of their work, by patches of gold leaf, which they place in favorable positions; they employ the above mordant. The manufacturers of paper hangings of the finer kinds attach gold and silver leaf to them by the same varnish.

MOROCCO. See LEATHER.

MORPHIA (*Morphine*, Fr.; *Morphin*, Germ.) is a vegeto-alkali which exists associated with opian, codeine, narcotine, meconine, meconic acid, resin, gum, bassorine, lignine, fat oil, caoutchouc, extractive, &c. in opium. Morphia is prepared as follows: Opium in powder is to be repeatedly digested with dilute muriatic acid, slightly heated, and sea-salt is to be added, to precipitate the opian. The filtered liquid is to be supersaturated with ammonia, which throws down the morphia, along with the meconine, resin, and extractive. The precipitate is to be washed with water, heated, and dissolved in dilute muriatic acid; the solution is to be filtered, whereby the foreign matters are separated from the salt of morphia, which concretes upon cooling, while the meconine remains in the acid liquid. The muriate of morphia having been squeezed between folds of blotting paper, is to be sprinkled with water, again squeezed, next dissolved in water, and decomposed by water of ammonia. The precipitate, when washed, dried, dissolved in alcohol, and crystallized, is morphia.

These crystals, which contain 6.32 per cent. of combined water, are transparent, colorless, four-sided prisms, without smell, and nearly void of taste, fusible at a moderate heat, and they concrete into a radiated translucent mass, but at a higher temperature they grow purple-red. Morphia consists of 72.34 of carbon; 6.366 of hydrogen; 5 of azote; and 16.3 of oxygen. It burns with a red and very smoky flame, is stained red by nitric acid, is soluble in 30 parts of boiling anhydrous alcohol, in 500 parts of boiling water, but hardly if at all in cold water, and is insoluble in ether and oils. The solutions have a strong bitter taste, and an alkaline reaction upon litmus paper. The saline compounds have a bitter taste, are mostly crystallizable, are soluble in water and alcohol (but not in ether), and give a blue color to the peroxyde salts of iron. It is a very poisonous substance. Acetate of morphia is sometimes prescribed, instead of opium, in medicine.

Preparation of Morphia.—The aqueous extract of opium is to be concentrated by evaporation, and mixed with chloride of tin, till no further precipitate appears. The liquid is then allowed to settle, is poured-off, the precipitate is washed, and the washings mixed with the poured-off liquid. To this mixture is then added ammonia, and the precipitate which it produces is to be digested with ether, in order to remove the narcotine; and then with alcohol, as long as the latter acquires a bitter taste. The alcohol being then partially removed by distillation, the pure morphia is obtained in the form of crystals.

MORTAR, HYDRAULIC, called also *Roman Cement*, is the kind of mortar used for building piers, or walls under or exposed to water, such as those of harbors, docks, &c. The poorer sorts of limestone are best adapted for this purpose, such as contain from 8 to 25 per cent of foreign matter, in silica, alumina, magnesia, &c. These though calcined, do not slake when moistened; but if pulverized they absorb water without swelling up or heating, like *fat lime*, and afford a paste which hardens in a few days under water, but in the air they never acquire much solidity. Smeaton first discovered these remarkable facts, and described them in 1759.

The following analyses of different hydraulic limestones, by Berthier, merit confidence [see next page]:—

No. 1 is from the fresh-water lime formation of Chateau-Landon, near Nemours; No. 2, the large-grained limestone of Paris; both of these afford a fat lime when burnt. Dolomite affords a pretty fat lime, though it contains 42 per cent. of carbonate of magnesia; No. 3 is a limestone from the neighborhood of Paris, which yields a poor lime, possessing no hydraulic property; No. 4 is the secondary limestone of Metz; No. 5 is the lime marl of Senonches, near Dreux; both the latter have the property of hardening under water, particularly the last, which is much used at Paris on this account.

All good hydraulic mortars must contain alumina and silica; the oxides of iron and manganese, at one time considered essential, are rather prejudicial ingredients. By adding silica and alumina, or merely the former, in certain circumstances, to fat lime, water-cement may be artificially formed; as also by adding to lime any of the following native productions, which contain silicates; puzzolana, trass or tarra, pumice-stone, salt-tuff, slate-clay. Puzzolana is a volcanic product, which forms hills of consider-

able extent to the south-west of the Apennines, in the district of Rome, the Pontine marshes, Viterbo, Bolsena, and in the Neapolitan region of Pozzuolo, whence the name. A similar volcanic tufa is found in many other parts of the world. According to Berthier, the Italian puzzolana consists of 44.5 silica; 15.0 alumina; 8.8 lime; 4.7 magnesia; 1.4 potash; 4.1 soda; 12 oxides of iron and titanium; 9.2 water; in 100 parts.

The *tufa* stone, which when ground forms *trass*, is composed of 57.0 silica, 16.0 clay, 2.6 lime, 1.0 magnesia, 7.0 potash, 1.0 soda, 5 oxydes of iron and titanium, 9.6 water. This tuff is found abundantly filling up valleys in beds of 10 or 20 feet deep, in the north of Ireland, among the schistose formations upon the banks of the Rhine, and at Monheim in Bavaria.

The fatter the lime, the less of it must be added to the ground puzzolana or trass, to form a hydraulic mortar; the mixture should be made extemporaneously, and must at any rate be kept dry till about to be applied. Sometimes a proportion of common sand mortar instead of lime is mixed with the trass. When the hydraulic cement hardens too soon, as in 12 hours, it is apt to crack; it is better when it takes 8 days to concrete. Through the agency of the water, silicates of lime, alumina, (magnesia,) and oxyde of iron are formed, which assume a stony hardness.

Besides the above two volcanic products, other native earthy compounds are used in making water cements. To this head belong all limestones which contain from 20 to 30 per cent. of clay and silica. By gentle calcination, a portion of the carbonic acid is expelled, and a little lime is combined with the clay, while a silicate of clay and lime results, associated with lime in a subcarbonated state. A lime-marl containing less clay will bear a stronger calcining heat without prejudice to its qualities as a hydraulic cement; but much also depends upon the proportion of silica present, and the physical structure of all the constituents.

The mineral substance most used in England for making such mortar is vulgarly called *cement-stone*. It is a reniform limestone, which occurs distributed in single nodules or rather lenticular cakes, in beds of clay. They are mostly found in those argillaceous strata which alternate with the limestone beds of the oolite formation, as also in the clay strata above the chalk, and sometimes in the London clay. On the coasts of Kent, in the isles of Sheppey and Thanet, on the coasts of Yorkshire, Somersetshire, and the Isle of Wight, &c., these nodular concretions are found in considerable quantities, having been laid bare by the action of the sea and weather. They were called by the older mineralogists *Septaria* and *Ludus Helmontii* (Van Helmont's coits.) When sawn across, they show veins of calc-spar traversing the silicious clay, and are then sometimes placed in the cabinets of *virtuosi*. They are found also in several places on the Continent, as at Neustadt-Eberswalde, near Antwerp, near Altdorf in Bavaria; as also at Boulogne-sur-mer, where they are called Boulogne-pebbles (*galets*). These nodules vary in size from that of a fist to a man's head; they are of a yellow-gray or brown color, interspersed with veins of calc-spar, and sometimes contain cavities bestudded with crystals.

Their specific gravity is 2.59.

No. 1. English cement-stone, analyzed by Berthier; No. 2. Boulogne stone, by Drapiez; No. 3. English ditto, by Davy; No. 4. reniform limestone nodules from Arkona, by Hühnefeld; No. 5. cement-stone of Avallon, by Dumas.

In England the stones are calcined in shaft-kilns, or sometimes in mound kilns, then, ground, sifted, and packed in casks. The color of the powder is dark-brown-red. When made into a thick paste with water, it absorbs little of it, evolves hardly any heat, and soon indurates. It is mixed with sharp sand in various proportions, immediately before using it; and is employed in all marine and river embankments, for securing the seams of stone or brick floors or arches from the percolation of moisture, and also for facing walls to protect them from damp.

The cement of Pouilly is prepared from a Jurassic (secondary) limestone, which contains 39 per cent. of silica, with alumina, magnesia, and iron oxide. Vicat forms a facitious Roman cement by making bricks with a pasty mixture of 4 parts of chalk, and 1 part of dry clay, drying, burning, and grinding them. River sand must be added to this powder; and even with this addition, its efficacy is somewhat doubtful; though it has, for want of a better substitute, been much employed at Paris.

The cement of Dill consists of porcelain or salt-glaze potsherds ground fine, and mixed with boiled linseed oil.

Hamelin's mastic or lithic paint to cover the façades of brick buildings, &c., is composed of 50 measures of silicious sand, 50 of lime-marl, and 9 of litharge or red-lead ground up with linseed oil.

Professor Kuhlmann, of Lisle, obtained a patent in April, 1841, in the name of Mr. Newton, for certain improvements in the manufacture of lime-cement and artificial stone; and of which he gave me a sample, possessed of a hardness and solidity fit for the sculptor.

In operating by the dry method, instead of calcining the limestone with sand and clay alone, as has been hitherto commonly practised, this inventor introduces a small quantity of soda, or, preferably, potash, in the state of sulphate, carbonate, or muriate; salts susceptible of forming silicates when the earthy mixture is calcined. The alkaline salt, equal in weight to about one-fifth that of the lime, is introduced in solution among the earths.

All sorts of lime are made hydraulic, in the humid way, by mixing slaked lime with solutions of common alum or sulphate of alumina; but the best method consists in employing a solution of the silicate of potash, called liquor of flints, or soluble glass, to mix in with the lime, or lime and clay. An hydraulic cement may also be made which will serve for the manufacture of architectural ornaments, by making a paste of pulverized chalk, with a solution of the silicate of potash. The said liquor of flints likewise gives chalk and plaster a stony hardness, by merely soaking them in it, after they are cut or moulded to a proper shape. On exposure to the air, they get progressively indurated. Superficial hardness may be readily procured by washing over the surface of chalk, &c., with liquor of flints, by means of a brush. This method affords an easy and elegant method of giving a stony crust to plastered walls and ceilings of apartments; as also to statues and busts, cast in gypsum, mixed with chalk.

The essential constituents of every good hydraulic mortar are caustic lime and silica; and the hardening of this compound under water consists mainly in a chemical combination of these two constituents through the agency of the water, producing a

hydrated silicate of lime. But such mortars may contain other bases besides lime, as for example clay and magnesia, whence double silicates of great solidity are formed; on which account dolomite is a good ingredient of these mortars. But the silica must be in a peculiar state for these purposes; namely, capable of affording a gelatinous paste with acids; and if not so already, it must be brought into this condition, by calcining it along with an alkali or an alkaline earth, at a bright red heat, when it will dissolve, and gelatinize in acids. Quartzose sand, however fine its powder may be, will form no water mortar with lime; but if the powder be ignited with the lime, it then becomes fit for hydraulic work. Ground felspar or clay forms with slaked lime no water cement; but when they are previously calcined along with the lime, the mixture becomes capable of hardening under water.

The mastic called *Hamelin's*, and so much employed in London, is composed of ground Portland stone (roe stone), sand and litharge in the proportion of 62 of the first, 35 of the second, and 3 of the third, in 100 parts; but other proportions will also answer the purpose. I find that chalk will not make a good mastic; being too compact to permit the air to insinuate between the pores, and to produce the concretion of the linseed oil, with which the above mixture is worked up and applied. This mastic soon acquires great hardness, and is totally impervious to water. The surface to which it is to be applied must be dry, and smeared over with linseed oil. Considerable dexterity is required to make good work with it. The fine dust of sandstone alone, mixed with 10 or 12 per cent. of litharge and 7 per cent. of linseed oil, forms an excellent mastic.

Limestone, which contains as much as 10 per cent. of clay, comports itself after calcination, if all the carbonic acid be expelled, just as pure limestone would do. When it is less strongly burned, it affords, however, a mass which hardens pretty speedily in water. If the argillaceous proportion of a marl amounts to 18 or 20 per cent., it still will slake with water, but it will absorb less of it, and forms a tolerably good hydraulic mortar, especially if a little good Roman cement be added to it. When the proportion of clay is 25 or 30 per cent. after burning, it heats but little with water, nor does it slake well, and must therefore be ground by stampers or an edge millstone, when it is to be used as a mortar. This kind of marl yields commonly the best water cement without other addition. Should the quantity of clay be increased farther, as up to 40 per cent., the compound will not bear a high or long-continued heat, without being spoiled for making hydraulic mortar after grinding to powder. When more strongly calcined, it forms a vitriform substance, and should, after being pulverized, be mixed up with good lime, to make a water mortar. If the marls, in any locality, differ much in their relative proportions of lime and alumina, as may be readily ascertained by the use of my lime-proof apparatus (see *Appendix*), then the several kinds should be mixed in such due proportions as to produce the most speedily setting, and most highly indurating hydraulic cement. See *SOILS, ANALYSIS* of.

MOSAIC GOLD. For the composition of this peculiar alloy of copper and zinc, called also *Or-molu*, Messrs. Parker and Hamilton obtained a patent in November, 1825. Equal quantities of copper and zinc are to be "melted at the lowest temperature that copper will fuse," which being stirred together so as to produce a perfect admixture of the metals, a further quantity of zinc is added in small portions, until the alloy in the melting pot becomes of the color required. If the temperature of the copper be too high, a portion of the zinc will fly off in vapor, and the result will be merely spelter or hard solder; but if the operation be carried on at as low a heat as possible, the alloy will assume first a brassy yellow color; then, by the introduction of small portions of zinc, it will take a purple or violet hue, and will ultimately become perfectly white; which is the appearance of the proper compound in its fused state. This alloy may be poured into ingots; but as it is difficult to preserve its character when re-melted, it should be cast directly into the figured moulds. The patentees claim the exclusive right of compounding a metal consisting of from 52 to 55 parts of zinc out of 100.

Mosaic gold, the *aurum musivum* of the old chemists, is a sulphuret of tin.

MOSAIC. (*Mosaïque*, Fr.; *Mosaisch*, Germ.) There are several kinds of mosaic, but all of them consist in imbedding fragments of different colored substances, usually glass or stones, in a cement, so as to produce the effect of a picture. The beautiful chapel of Saint Lawrence in Florence, which contains the tombs of the Medici, has been greatly admired by artists, on account of the vast multitude of precious marbles, jaspers, agates, aventurines, malachites, &c., applied in mosaic upon its walls. The detailed discussion of this subject belongs to a treatise upon the fine arts.

MOTHER OF PEARL (*Nacre de Perles*, Fr.; *Perlen mutter*, Germ.) is the hard, silvery, brilliant internal layer of several kinds of shells, particularly oysters, which is often variegated with changing purple and azure colors. The large oysters of the Indian seas alone secrete this coat of sufficient thickness to render their shells available to the purposes of manufactures. The genus of shell fish called *pentadina* furnish the finest pearls, as well as mother of pearl; it is found in greatest perfection round

coasts of Ceylon, near Ormus in the Persian Gulf, at Cape Comorin, and among some of the Australian seas. The brilliant hues of mother of pearl do not depend upon the nature of the substance, but upon its structure. The microscopic wrinkles or furrows which run across the surface of every slice, act upon the reflected light in such a way as to produce the chromatic effect; for Sir David Brewster has shown, that if we take, with very fine black wax, or with the fusible alloy of D'Arcet, an impression of mother of pearl, it will possess the iridescent appearance. Mother of pearl is very delicate to work, but it may be fashioned by saws, files, and drills, with the aid sometimes of a corrosive acid, such as the dilute sulphuric or muriatic; and it is polished by coleothar of vitriol.

MOTHER-WATER is the name of the liquid which remains after all the salts that will regularly crystallize have been extracted, by evaporation and cooling, from any saline solution.

MOUNTAIN SOAP (*Savon de montagne*, Fr.; *Bergseife*, Germ.) is a tender mineral, soft to the touch, which assumes a greasy lustre when rubbed, and falls to pieces in water. It consists of silica 44, alumina 26.5, water 20.5, oxide of iron 8, lime 0.5. It occurs in beds, alternating with different sorts of clay, in the Isle of Skye, at Billin in Bohemia, &c. It has been often, but improperly, confounded with scatite.

MUCIC ACID (*Acide mucique*, Fr.; *Schleimsäure*, Germ.) is the same as the saccharic acid of Scheele, and may be obtained by digesting one part of gum arabic, sugar of milk, or pectic acid, with twice or thrice their weight of nitric acid. It forms white granular crystals, and has not been applied to any use in the arts.

MUCILAGE is a solution in water of gummy matter of any kind.

MUFFLE is the earthenware case or box, in the assay furnaces, for receiving the crucibles, and protecting them from being disturbed by the fuel. See ASSAY and FURNACE.

MUNDIC is the name of copper pyrites among English miners.

MUNJEET is a kind of madder grown in several parts of India.

MURIATIC or HYDROCHLORIC ACID; anciently *marine acid*, and *spirit of salt*. (*Acide hydrochlorique*, and *Chlorhydrique*, Fr.; *Salzsäure*, Germ.) This acid is now extracted from sea-salt, by the action of sulphuric acid and a moderate heat; but it was originally obtained from the salt by exposing a mixture of it and of common clay to ignition in an earthen retort. The acid gas which exhales, is rapidly condensed by water. 100 cubic inches of water are capable of absorbing no less than 48,000 cubic inches of the acid gas, whereby the liquid acquires a specific gravity of 1.2109; and a volume of 142 cubic inches. This vast condensation is accompanied with a great production of heat, whence it becomes necessary to apply artificial refrigeration, especially if so strong an acid as the above is to be prepared. In general, the muriatic acid of commerce has a specific gravity varying from 1.15 to 1.20; and contains, for the most part, considerably less than 40 parts by weight of acid gas in the hundred. The above stronger acid contains 42.68 per cent. by weight; for since a cubic inch of water, which weighs 252.5 grains, has absorbed 480 cubic inches = 188 grains of gas; and $252.5 + 188 = 440.5$; then $440.5 : 188 :: 100 : 42.68$. In general a very good approximation may be found to the percentage of real muriatic acid, in any liquid sample, by multiplying the decimal figures of the specific gravity by 200. Thus for example, at 1.162 we shall have by this rule $0.162 \times 200 = 32.4$, for the quantity of gas in 100 parts of the liquid. Muriatic acid gas consists of chlorine and hydrogen combined, without condensation, in equal volumes. Its specific gravity is 1.247, air = 1.000.

By sealing up muriate of ammonia and sulphuric acid, apart, in a strong glass tube reversed, and then causing them to act on each other, Sir H. Davy procured liquid muriatic acid. He justly observes, that the generation of elastic substances in close vessels, either with or without heat, offers much more powerful means of approximating their molecules than those dependant on the application of cold, whether natural or artificial; for as gases diminish only $\frac{1}{480}$ in volume for every degree of Fahrenheit's scale, beginning at ordinary temperatures, a very slight condensation only can be produced by the most powerful freezing mixtures, not half as much as would result from the application of a strong flame to one part of a glass tube, the other part being of ordinary temperature; and when attempts are made to condense gases into liquids by sudden mechanical compression, the heat instantly generated presents a formidable obstacle to the success of the experiment; whereas in the compression resulting from their slow generation in close vessels, if the process be conducted with common precautions, there is no source of difficulty or danger; it may be easily assisted by artificial cold, in cases where gases approach near to the point of compression and temperature at which they become vapors.—*Phil. Trans.* 3.

The muriatic acid of commerce has usually a yellowish tinge, but when chemically pure is colorless. It fumes strongly in the air, emitting a corrosive vapor of a peculiar smell. The characteristic test of muriatic acid in the most dilute state, is nitrate of silver, which causes a curdy precipitate of chloride of silver.

The preparation of this acid upon the great scale is frequently effected in this country

by acting upon sea-salt in hemispherical iron pots, or in cast-iron cylinders, with concentrated sulphuric acid; taking 6 parts of the salt to 5 of the acid. The mouth of the pot may be covered with a slab of silicious freestone, perforated with two holes of about two inches in diameter each, into the one of which the acid is poured by a funnel in successive portions, and into the other a bent glass, or stone-ware tube, is fixed, for conducting the disengaged muriatic gas into a series of large globes of bottle glass, one-third filled with water, and laid on a sloping sand-bed. A week is commonly employed for working off each pot; no heat being applied to it till the second day.

The decomposition of sea-salt by sulphuric acid, was at one time carried on by some French manufacturers in large leaden pans, 10 feet long, 5 feet broad, and a foot deep, covered with sheets of lead, and luted. The disengaged acid gas was made to circulate in a conduit of glazed bricks, nearly 650 yards long, where it was condensed by a sheet of water exceedingly thin, which flowed slowly in the opposite direction of the gas down a slope of 1 in 200. At the end of this canal nearest the apparatus, the muriatic acid was as strong as possible, and pretty pure; but towards the other end, the water was hardly acidulous. The condensing part of this apparatus was therefore tolerably complete; but as the decomposition of the salt could not be finished in the leaden pans, the acid mixture had to be drawn out of them, in order to be completely decomposed in a reverberatory furnace; in this way nearly 50 per cent. of the muriatic acid was lost. And besides, the great quantity of gas given off during the emptying of the lead-chambers was apt to suffocate the workmen, or seriously injured their lungs, causing severe hemoptysis. The employment of muriatic acid is so inconsiderable, and the loss of it incurred in the preceding process is of so little consequence, that subsequently, both in France and in England, sulphate of soda, for the soda manufacture, has been procured with the dissipation of the muriatic acid in the air. In the method more lately resorted to, the gaseous products are discharged into extensive vaults, where currents of water condense them and carry them off into the river. The surrounding vegetation is thereby saved in some measure from being burned up, an accident which was previously sure to happen when fogs precipitated the floating gases upon the ground. At Newcastle, Liverpool, and Marseilles, where the consumption of muriatic acid bears no proportion to the manufacture of soda, this process is now practised upon a vast scale.

The apparatus for condensing muriatic acid gas has been modified and changed, of late years, in many different ways.

The Bastringue apparatus. At the end of a reverberatory furnace, (see CO^{IN}, SMELTING OF, and SODA, MANUFACTURE OF,) a rectangular lead trough or pan, about 1 foot deep, of a width equal to that of the interior of the furnace, that is, about 5 feet 6 in. and 6½ feet long, is incased in masonry, having its upper edges covered with cast-iron plates or fire tiles, and placed upon a level with the passage of the flame, as it escapes from the reverberatory. The arch which covers that pan forms a continuation of the roof of the reverberatory, and is of the same height. The flame which proceeds from the furnace containing the mixture of salt and sulphuric acid is made to escape between the vault and the surface of the iron plates or fire tiles, through a passage only 4 in. in height. When the burned air and vapors reach the extremity of the pan, they are reflected downwards, and made to return beneath the bottom of the pan, in a flue, which is afterwards divided so as to lead the smoke into two lateral flues, which terminate in the chimney. The pan is thus surrounded as it were with the heat and flame discharged from the reverberatory furnace. See EVAPORATION. A door is opened near the end of the pan, for introducing the charge of sea-salt, amounting to 12 bags of 2 cwt. each, or 24 cwt. This door is then luted on as tightly as possible, and for every 100 parts of salt, 110 of sulphuric acid are poured in, of specific gravity 1.594, containing 57 per cent. of dry acid. This acid is introduced through a funnel inserted in the roof of the furnace. Decomposition ensues, muriatic acid gas mingled with steam is disengaged, and is ducted through 4 stone-ware tubes into the refrigerators, where it is finally condensed. These refrigerators consist of large stone-ware earthenware carboys, called *dame-jeans* in France, the number of 7 or 8 for each pipe, and arranged so that the neck of the one communicates with the body of the other; thus the gas must traverse the whole series, and is in a good measure condensed by the water in them, before reaching the last.

When the operation is finished, the door opposite the pan is opened, and the residue in it is discharged, in the form of a fluid magma, upon a square bed of bricks, external to the furnace. This paste speedily concretes on cooling, and is then broken into fragments and carried to the soda manufactory. The immense quantity of gas exhaled in discharging the pan, renders this part of the operation very painful to the workmen, and wasteful in reference to the production of muriatic acid. The difficulty of luting securely the cast-iron plates or fire tiles which cover the pan, the impossibility of completing the decomposition of the salt, since the residuum must be run off in a liquid state, finally, the damage sustained by the melting and corrosion of the lead, &c., are among the causes why no more than 80 or 90 parts of muriatic acid at 1.170 are collected,

equivalent to 25 per cent. of real acid for every 100 of salt employed, instead of much more than double that quantity, which it may be made to yield by a well conducted chemical process.

The *cylinder apparatus* is now much esteemed by many manufacturers. *Fig. 982* represents, in transverse section, a bench of iron cylinder retorts, as built up in a proper furnace for producing muriatic acid; and *fig. 983*, a longitudinal section of one retort

with one of its carboys of condensation. *a* is the grate; *b*, a fireplace, in which two iron cylinders, *c c*, are set alongside of each other. They are $5\frac{1}{2}$ feet long, 20 inches in

diameter, about $\frac{1}{2}$ of an inch thick, and take 1.6 cwt. of salt for a charge; *d* is the ash-pit; *e, e*, are cast-iron lids, for closing both ends of the cylinders; *f* is a tube in the posterior lid, for pouring in the sulphuric acid; *g* is another tube, in the anterior lid, for the insertion of the bent pipe of hard glazed stone-ware *h*; *i* is a three-necked stone-ware carboy; *k* is a tube of safety; *l*, a tube of communication with the second carboy; *m m, m m*, are the flues leading to the chimney *n*.

After the salt has been introduced, and the fire kindled, $83\frac{1}{2}$ per cent. of its weight of sulphuric acid, of spec. grav. 1.80, should be slowly poured into the cylinder through a lead funnel, with a syphon-formed pipe. The three-necked carboys may be either placed in a series for each retort, like a range of Woulfe's bottles, or all the carboys of the front range may be placed in communication with one another, while the last carboy at one end is joined to the first of the second range; and thus in succession. They must be half filled with cold water; and when convenient, those of the front row at least, should be plunged in an oblong trough of running water. The acid which condenses in the carboys of that row is apt to be somewhat contaminated with sulphuric acid, muriate of iron, or even sulphate of soda; but that in the second and third will be found to be pure. In this way 100 parts of sea-salt will yield 130 parts of muriatic acid, of spec. grav. 1.19; while the sulphate of soda in the retort will afford from 208 to 210 of that salt in crystals.

It is proper to heat all the parts of the cylinders equally, to ensure the simultaneous decomposition of the salt, and to protect it from the acid; for the hotter the iron, and the stronger the acid, the less erosion ensues.

Some manufacturers, with the view of saving fuel by the construction of their furnaces, oppose to the flame as many obstacles as they can, and make it perform numerous circulations round the cylinders; but this system is bad, and does not even effect the desired economy, because the passages, being narrow, impair the draught, and become speedily choked up with the soot, which would be burned profitably in a freer space; the decomposition also, being unequally performed, is less perfect, and the cylinders are more injured. It is better to make the flame envelope at once the body of the cylinder; after

which it may circulate beneath the vault, in order to give out a portion of its caloric, before it escapes at the chimney.

The fire should be briskly kindled, but lowered as soon as the distillation commences; and then continued moderate till the evolution of gas diminishes, when it must be heated somewhat strongly to finish the decomposition. The iron door is now removed to extract the sulphate of soda, and to recommence another operation. This sulphate ought to be white and uniform, exhibiting in its fracture no undecomposed sea-salt.

Liquid muriatic acid has a very sour corrosive taste, a pungent suffocating smell, and acts very powerfully upon a vast number of mineral, vegetable, and animal substances. It is much employed for making many metallic solutions; and in combination with nitric acid, it forms the aqua regia of the alchemists, so called from its property of dissolving gold.

Table of Muriatic Acid, by Dr. Ure.

Acid of 120 in 100	Specific gravity.	Chlorine.	Muriatic Gas.	Acid of 120 in 100	Specific gravity.	Chlorine.	Muriatic Gas.	Acid of 120 in 100	Specific gravity.	Chlorine.	Muriatic Gas.

In treating of soda, we shall have occasion to comment upon the formation of muriatic acid; and therefore it is unnecessary to enter into the details of that operation here. The purest commercial muriatic acid commonly contains sulphureous acid in considerable quantity, which unfits it for many purposes, and ought therefore to be guarded against; but more than this, when made from sulphuric acid containing arsenic, it is invariably contaminated with that poisonous substance, and hence, those persons who are in the habit of making what is called digestive bread, by an admixture of bicarbonate of soda and muriatic acid with the flour they employ, cannot be too careful in going to none but the most respectable sources for their acid; as an enormous amount of rough muriatic acid is constantly passing through the market positively loaded with arsenious impurity. For the same reason, as chloride of lime is manufactured from the acid, it must be regarded with a cautious eye; as, during the action of such muriatic acid upon peroxide of manganese, a highly volatile chloride of arsenic

passes off with the chlorine gas, and is condensed like it by the lime. Since, however, this, in the end, becomes arsenite of lime, a salt almost insoluble in water, the tendency to mischief is greatly diminished. Nevertheless, as in some medico-legal works it is recommended to sprinkle cadaverous exhumations with chloride of lime, the ends of justice may easily be perverted or prevented, if due care be not employed to ascertain beforehand that the chloride of lime is pure. Very little indeed of that to be met with in commerce will bear a careful analytical investigation.

MURIATES were, till the great chemical era of Sir H. Davy's researches upon chlorine, considered to be compounds of an undecomposed acid, the muriatic, with the different bases; but he proved them to be, in reality, compounds of chlorine with the metals. They are all, however, still known in commerce by their former appellation. The only muriates much used in the manufactures are, *Muriate of ammonia* or *SAL-AMMONIAC*; *muriated peroxide of mercury*, *MERCURY*, *bichloride of*; *muriate of soda*, or *chloride of sodium*, see *SALT*; *muriate of tin*, see *CALICO-PRINTING* and *TIN*; *Submuriate of mercury* or *CALOMEL*.

MUSK (*Musc*, Fr.; *Moschus*, Germ.); is a peculiar aromatic substance, found in a sac between the navel and the parts of generation of a small male quadruped of the deer kind, called by Linnaeus *Moschus moschiferus*, which inhabits Tonquin and Thibet. The color of musk is blackish-brown; it is lumpy or granular, somewhat like dried blood, with which substance, indeed, it is often adulterated. The intensity of its smell is almost the only criterion of its genuineness. When thoroughly dried it becomes nearly scentless; but it recovers its odor when slightly moistened with water of ammonia. The Tonquin musk is most esteemed. It comes to us in small bags covered with a reddish-brown hair; the bag of the Thibet musk is covered with a silvery-gray hair. All the analyses of musk hitherto made teach little or nothing concerning its active or essential constituent. It is used in medicines, and is an ingredient in a great many perfumes.

The musk deer, from the male of which animal species the bag containing this valuable drug is obtained, is a native of the mountainous Kirgesian and Langorian steppes of the Altai, on the river Irtysh, extending eastwards as far as the river Jenisei and Lake Baikal; and generally of the mountains of Eastern Asia, between 30° and 60° of N. Lat. Two distinct kinds of musk are known in commerce, the first being the Chinese Tonquin, Thibetian or Oriental, and the Siberian or Russian. The Chinese is regarded by Dr. Goebel as the result of ingenious adulterations of the genuine article by that crafty people. The Russian musk is genuine, the bags never being opened, are consequently never sewn, nor artificially closed, like those imported into London from China. The former is sometimes so fresh, that moisture may be expressed from the bag by cutting through its fleshy side. The interior mass is frequently of a soft and pappy consistence; but the surface of the bag is perfectly dry. The Chinese bags are found invariably to have been opened and again glued together, more or less neatly; though sometimes the stitches of the sewing are manifest. Mr. Dryssen, an eminent merchant at St. Petersburg, states that during the many years he has been in the trade, although he has received at a time from 100 to 200 ounces from London, yet in no case whatever has he met with a bag which had not been opened, and closed with more or less ingenuity. The genuine contents seem to have been first removed, modified, and replaced. M. Guibourt gives the following as the constituents of a Chinese musk bag: 1, water; 2, ammonia; 3, solid fat or stearine; 4, liquid fat or elaine; 5, cholesterine; 6, acid oil, combined with ammonia; 7, volatile oil; 8-10, hydrochlorates of ammonia, potassa, and lime; 11, an undetermined acid; 12, gelatine; 13, albumen; 14, fibrine; 15, carbonaceous matter, soluble in water; 16, calcareous salt; 17, carbonate of lime; 18, hairs and sand.

From June 1841 to June 1842, a duty of 6d. per oz. was paid at the port of London alone upon 969 ounces of musk. The prices of grain musk of the best quality (the matter without the bag) varies from 60s. to 95s. per oz.

There is a superior musk imported now from the United States, which is nearly free from the carbonate of lime, so abundant in the bags of the Siberian musk.

MUSLIN, is a fine cotton fabric, used for ladies' robes; which is worn either white, dyed, or printed.

MUSQUET. It is now twenty-two years since the Hon. Board of Ordnance, with the view of introducing the use of percussion fire-arms into the British Army, employed me to investigate experimentally the best mode of preparing the priming powder for that purpose. The result of these experiments was presented in a report, the substance of which is given under the article *FULMINATE* in this Dictionary. During this long interval, Mr. Lovell, inspector of small arms for her Majesty's service, and director of the Royal manufactory, at Enfield Chase, has directed his ingenious mind to the construction of a sure, simple, and strong musquet, with which, under his able superintendence, the whole of her Majesty's soldiers are now provided. He has also

furnished them with a short, but clear set of instructions for the cleaning and management of these excellent arms, illustrated by a series of wood engravings. From this little work, the following notice is copied.

Fig. 984. The barrel, reduced to one-seventh size. *a*, the breech; *b*, the nipple-seat or lump; *c*, the back-sight; *d*, the back loop; *e*, the middle loop; *f*, the swivel-loop; *g*, the front-loop with the bayonet spring attached; *h*, the front sight; *i*, the muzzle.

Fig. 985. The breech-pin, half size; *a*, the tang; *b*, the neck; *c*, the screw threads; *d*, the face.

Fig. 986. The bayonet-spring, two ways, half size. *a*, the shank; *b*, the neck; *c*, the hook; *d*, the mortice.

Fig. 987. The nipple, full size. *a*, the cone; *b*, the squares; *c*, the shoulder; *d*, the screw-threads; *e*, the touch-hole.

Fig. 988. The rammer, reduced to one-seventh size. *a*, the head; *b*, the shaft; *c*, the screw-threads.

Fig. 989. The lock outside, half size. *a*, the plate; *b*, the cock; *c*, the tumbler-pin; *d*, the hollow for the nipple seat.

Fig. 990. The lock inside, half size, showing all the parts in their places with the cock down at bearer. *a*, the main-spring; *b*, the sear-spring; *c*, the sear; *d*, the tumbler;

i, the bridle; *f*, the main-spring; *g*, the sear-pin; *h*, the sear-spring-pin; *i*, the bridle-pin.

MUST is the sweet juice of the grape.

MUSTARD (*Moutarde*, Fr.; *Senf*, Germ.) is a plant which yields the well-known seed used as a condiment to food. M. Lenormand gives the following prescription for preparing mustard for the table.

With 2 pounds of very fine flour of mustard, mix half an ounce of each of the following fresh plants; parsley, chervil, celery, and tarragon, along with a clove of garlic, and twelve salt anchovies, all well minced. The whole is to be triturated with the flour of mustard till the mixture becomes uniform. A little grape-must or sugar is to be added, to give the requisite sweetness; then one ounce of salt, with sufficient water to form a thin paste by rubbing in a mortar. With this paste the mustard pots being nearly filled, a redhot poker is to be thrust down into the contents of each, which removes (it is said) some of the acrimony of the mustard, and evaporates a little water, so as to make room for pouring a little vinegar upon the surface of the paste. Such table mustard not only keeps perfectly well, but improves with age.

The mode of preparing table mustard patented by M. Soyés, consisted in steeping mustard seed in twice its bulk of weak wood vinegar for eight days, then grinding the whole into paste in a mill, putting it into pots, and thrusting a redhot poker into each of them.

MUTAGE is a process used in the south of France to arrest the progress of fermentation in the must of the grape. It consists either in diffusing sulphurous acid, from burning sulphur matches in the cask containing the must, or in adding a little sulphite (not salphate) of lime to it. The last is the best process. See FERMENTATION.

MYRICINE is a vegetable principle which constitutes from 20 to 30 per cent. of the weight of bees-wax, being the residuum from the solvent action of alcohol upon that

substance. It is a grayish-white solid, which may be vaporized almost without alteration.

MYRRH is a gum-resin, which occurs in tears of different sizes; they are reddish-brown, semi-transparent, brittle, of a shining fracture, appear as if greasy under the pestle, they have a very acrid and bitter taste, and a strong, not disagreeable, smell. Myrrh flows from the incisions of a tree not well known, which grows in Arabia and Abyssinia, supposed to be a species of *amyris* or *mimosa*. It consists of resin and gum in proportions stated by Pelletier at 31 of the former and 66 of the latter; but by Braconot, at 23 and 77. It is used only in medicine.

N.

NACARAT is a term derived from the Spanish word *nacar*, which signifies mother of pearl; and is applied to a pale red color, with an orange cast. See CALICO-PRINTING. The *nacaral* of Portugal or *Bezetta* is a crape or fine linen fabric, dyed fugitively of the above tint, which ladies rub upon their countenances to give them a roseate hue. The Turks of Constantinople manufacture the brightest red crapes of this kind. See ROUGE.

NAILS, MANUFACTURE OF. (*Clou*, Fr.; *Nagel*, Germ.)

The forging of nails was till of late years a handicraft operation, and therefore belonged to a book of trades, rather than to a dictionary of arts. But several combinations of machinery have been recently employed, under the protection of patents, for making these useful implements, with little or no aid of the human hand; and these deserve to be noticed, on account both of their ingenuity and importance.

As nails are objects of prodigious consumption in building their block-houses, the citizens of the United States very early turned their mechanical genius to good account in the construction of various machines for making them. So long since as the year 1810, it appears, from the report of the secretary of their treasury, that they possessed a machine which performed the cutting and heading at one operation, with such rapidity that it could turn out upwards of 100 nails per minute. "Twenty years ago," says the secretary of the state of Massachusetts, in that report, "some men, then unknown, and then in obscurity, began by cutting slices out of old hoops, and, by a common vice gripping these pieces, headed them with several strokes of the hammer. By progressive improvements, slitting-mills were built, and the shears and the heading tools were perfected; yet much labor and expense were requisite to make nails. In a little time Jacob Perkins, Jonathan Ellis, and a few others, put into execution the thought of cutting and of heading nails by water power; but, being more intent upon their machinery than upon their pecuniary affairs, they were unable to prosecute the business. At different times other men have spent fortunes in improvements and it may be said with truth that more than one million of dollars has been expended; but at length these joint efforts are crowned with complete success, and we are now able to manufacture, at about one third of the expense that wrought nails can be manufactured for, nails which are superior to them for at least three fourths of the purposes to which nails are applied, and for most of those purposes they are full as good. The machines made use of by Odiorne, those invented by Jonathan Ellis, and a few others, present very fine specimens of American genius.

"To northern carpenters, it is well known that in almost all instances it is unnecessary to bore a hole before driving a cut nail; all that is requisite is, to place the cutting edge of the nail across the grain of the wood; it is also true, that cut nails will hold better in the wood. These qualities are, in some rough building works, worth twenty per cent. of the value of the article, which is equal to the whole expense of manufacturing. For sheathing and drawing, cut nails are full as good as wrought nails; only in one respect are the best wrought nails a little superior to cut nails, and that is where it is necessary they should be clinched. The manufacture of cut nails was born in our country, and has advanced, within its bosom, through all the various stages of infancy to manhood; and no doubt we shall soon be able, by receiving proper encouragement, to render them superior to wrought nails in every particular.

"The principal business of rolling and slitting-mills, is rolling nail plates; they also serve to make nail rods, hoops, tires, sheet iron, and sheet copper. In this State we have not less than twelve.

"These mills could roll and slit 7000 tons of iron a year; they now, it is presumed, roll and slit each year about 3500 tons, 2400 tons of which, probably, are cut up into nails and brads, of such a quality that they are good substitutes for hammered nails, and, in fact, have the preference with most people, for the following reasons; viz., on account of the sharp corner and true taper with which cut nails are formed; they may be driven into harder wood without bending or breaking, or hazard of splitting the wood, by which

the labor of boring is saved, the nail one way being of the same breadth or thickness from head to point."

Since the year 1820, the following patents have been obtained in England for making nails; many of them of American origin:—

Alexander Law, September, 1821, for nails and bolts for ships' fastenings, made in a twisted form, by hand labor.

Glascott and Mitchell, December, 1823, for ship nails with rounded heads, by hand labor.

Wilkes and Ecroyd, November, 1825, for an engine for cutting wedge-form pieces from plates.

Ledsom and Jones, December 11, 1827, for machinery for cutting brads and sprigs from plates; it does not form heads.

The first nail apparatus to which I shall particularly advert, is due to Dr. Church; it was patented in his absence by his correspondent, Mr. Thomas Tyndall, of Birmingham, in December, 1827. It consists of two parts; the first is a mode of forming nails, and the shafts of screws, by pinching or pressing ignited rods of iron between indented rollers; the second produces the threads on the shafts of the screws previously pressed. The metallic rods, by being passed between a pair of rollers, are rudely shaped, and then cut asunder between a pair of shears; after which they are pointed and headed, or otherwise brought to their finished forms, by the agency of dies placed in a revolving cylinder. The several parts of the mechanism are worked by toothed wheels, cams, and levers. The second part of Dr. Church's invention consists of a mechanism for cutting the threads of screws to any degree of obliquity or form.*

Mr. L. W. Wright's (American) apparatus should have been mentioned before the preceding, as the patent for it was sealed in March of the same year; though an amended patent was obtained in September, 1828. Its object was to form metal screws for wood. I have seen the machinery, but consider it much too complex to be described in the present work.

Mr. Edward Hancorne, of Skinner street, London, nail manufacturer, obtained a patent in October, 1828, for a nail making-machine, of which a brief description may give my readers a conception of this kind of manufacture. Its principles are similar to those of Dr. Church's more elaborate apparatus.

The rods or bars having been prepared in the usual way, either by rolling or hammering, or by cutting from sheets or plates of iron, called slitting, are then to be made red-hot, and in that state passed through the following machine, whereby they are at once cut into suitable lengths, pressed into wedge forms for pointing at the one end, and stamped at the other end to produce the head. A longitudinal view of the machine is shown in fig. 991. A strong iron frame-work, of which one side is shown at *a a*, supports the whole of the mechanism. *b* is a table capable of sliding to and fro horizontally.

Upon this table are the clamps, which lay hold of the sides of the rod as it advances; and also the shears which cut the rod into nail lengths.

These clamps or holders consist of a fixed piece and a movable piece; the latter being brought into action by a lever. The rod or bar of iron shown at *c*, having been made red hot, is introduced into the machine by sliding it forward upon the table *b*, when the table is in its most advanced position; rotatory motion is then given to the crank shaft *d*,

* For further details, see Newton's Journal, 2nd series, vol. III. p. 194.

by means of a band passing round the rigger pulley *e*, which causes the table *b* to be drawn back by the crank rod *f*: and as the table recedes, the horizontal lever is acted upon, which closes the clamps. By these means the clamps take fast hold of the sides of the heated rod, and draw it forward, when the moveable chap of the shears, also acted upon by a lever, slides laterally, and cuts off the end of the rod held by the clamps: the piece thus separated is destined to form one nail.

Suppose that the nail placed at *g*, having been thus brought into the machine and cut off, is held between clamps, which press it sideways (these clamps are not visible in this view); in this state it is ready to be headed and pointed.

The header is a steel die *h*, which is to be pressed up against the end of the nail by a cam *i*, upon the crank-shaft; which cam, at this period of the operation, acts against the end of a rod *k*, forming a continuation of the die *h*, and forces up the die, thus compressing the metal into the shape of a nail-head.

The pointing is performed by two rolling snail pieces or spirals *l, l*. These pieces are somewhat broader than the breadth of the nail; they turn upon axles in the side frames. As the table *b* advances, the racks *m*, on the edge of this table, take into the toothed segments *n, n*, upon the axles of the spirals, and cause them to turn round.

These spirals pinch the nail at first close under its head with very little force; but as they turn round, the longer radius of the spiral comes into operation upon the nail, so as to press its substance very strongly, and squeeze it into a wedge form. Thus the nail is completed, and is immediately discharged from the clamps or holders. The carriage is then again put in motion by the rotation of the crank-shaft, which brings another portion of the rod *c* forward, cuts it off, and then forms it into a nail.

Richard Prosser, July, 1831, for making tacks for ornamental furniture, by soldering or wedging the spike into the head. This also is the invention of Dr. Church.

Dr. William Church, February, 1832, for improvements in machinery for making nails. These consist, first, in apparatus for forming rods, bars, or plates of iron, or other metals; secondly, in apparatus for converting the rods, &c., into nails; thirdly, in improvements upon Prosser's patent. The machinery consists in laminating rollers, and compressing dies.

The method of forming the rods from which the nails are to be made, is very advantageous. It consists in passing the bar or plate iron through pressing rollers, which have indentations upon the peripheries of one or both of them, so as to form the bar or plate into the required shape for the rods, which may be afterwards separated into rods of any desired breadth, by common slitting rollers.

The principal object of rolling the rods into these wedge forms, is to measure out a quantity of metal duly proportioned to the required thickness or strength of the nail in its several parts; which quantity corresponds to the indentations of the rollers.

Thomas John Fuller, February 27, 1834, for an improved apparatus for making square-pointed, and also flat-pointed nails. He claims as his invention, the application of vertical and horizontal hammers (mounted in his machine) combined for the purpose of tapering and forming the points of the nails; which, being made to act alternately, resemble hand work, and are therefore not so apt to injure the fibrous texture of the iron, he imagines, as the rolling machinery is. He finishes the points by rollers.

Miles Berry, February 19, 1834, for machinery for forming metal into bolts, rivets, nails, and other articles; being a communication from a foreigner residing abroad. He employs in his machine holding chaps, heading dies, toggle joints, cams, &c., mechanisms apparently skilfully contrived, but too complex for admission under the article *nail* in this volume.

William Southwood Stocker, July, 1836. This is a machine apparently of American parentage, as it has the same set of features as the old American mechanisms of Perkins and Dyer, at the Britannia Nail-works, Birmingham, and all the other American machines since described, for pressing metal into the forms of nails, pins, screw-shafts, rivets, &c.; for example, it possesses pressers or hammers for squeezing the rods of metal, and forming the shanks, which are all worked by a rotatory action; cutters for separating the appropriate lengths, and dies for forming the heads by compression, also actuated by revolving cams or cranks.

Mr. Stocker intends, in fact, to effect the same sorts of operations by automatic mechanisms as are usually performed by the hands of a nail-maker with his hammer and anvil; viz., the shaping of a nail from a heated rod of iron, cutting it off at the proper length, and then compressing the end of the metal into the form of the head. His machine may be said to consist of two parts, connected in the same frame; the one for shaping the shank of the nail, the other for cutting it off and heading it. The frame consists of a strong table to bear the machinery. Two pairs of hammers, formed as levers, the one pair made to approach each other by horizontal movements, the other pair by vertical movements, are the implements by which a portion at the end of a red-hot rod of iron is beaten or pressed into the wedge-like shape of the shaft of a nail. This having been

done, and the rod being still hot, is withdrawn from the beaters, and placed in the other part of the machine, consisting of a pair of jaws like those of a vice, which pinch the shank of the nail and hold it fast. A cutter upon the side of a wheel now comes round, and, by acting as the moving chap of a pair of shears, cuts the nail off from the rod. The nail shank being still firmly held in the jaws of the vice, with a portion of its end projecting outwardly, the heading die is slidden laterally until it comes opposite to the end of the nail; the die is then projected forward with great force, for the purpose of what is termed upsetting the metal at the projecting end of the nail, and thereby blocking out the head.

A main shaft, driven by a band and rigger as usual, brings, as it revolves, a cam into operation upon a lever which carries a double inclined plane or wedge in its front or acting part. This wedge being by the rotatory cam projected forwards between the tails of one of the pairs of hammers, causes the faces of these hammers to approach each other, and to beat or press the redhot iron introduced between them, so as to flatten it upon two opposite sides. The rotatory cam passing round, the wedge lever is relieved, when springs instantly throw back the hammers; another cam and wedge-lever now brings the second pair of hammers to act upon the other two sides of the nail in a similar way. This is repeated several times, until the end of the redhot iron rod, gradually advanced by the hands of the workman, has assumed the desired form, that is, has received the bevel and point of the intended nail.

The rod is then withdrawn from between the hammers, and in its heated state is introduced between the jaws of the holders, for cutting off and finishing the nail. A bevel pinion upon the end of the main shaft, takes into and drives a wheel upon a transverse shaft, which carries a cam that works the lever of the holding jaws. The end of the rod being so held in the jaws or vice, a cutter at the side of a wheel upon the transverse shaft separates, as it revolves, the nail from the end of the rod, leaving the nail firmly held by the jaws. By means of a cam, the heading die is now slidden laterally opposite to the end of the nail in the holding jaws, and by another cam, upon the main shaft, the die is forced forward, which compresses the end of the nail, and spreads out the nail into the form of a head. As the main shaft continues to revolve, the cams pass away, and allow the spring to throw the jaws of the vice open, when the nails fall out; but to guard against the chance of a nail sticking in the jaws, a picker is provided, which pushes the nail out as soon as it is finished.

In order to produce round shafts, as for screw blanks, bolts, or rivets, the faces of the hammers, and the dies for heading, must be made with suitable concavities.

NAILS. (*Exhibition.*) John Reynolds, Crown Nail Works, Newton Row, Birmingham, Manufacturer.

A case enclosing a card of cut nails, consisting of upwards of 200 distinct varieties of the most useful strengths and sizes, made of iron, zinc, brass, and copper.

In this manufacture sheets of iron of the proper thickness are cut across by a pair of cutting edges, which are set in motion by machinery; the breadth of these strips is equivalent to the length of the nails to be produced from them; the strip, for the convenience of turning, is fastened into a pair of grips attached to a wood shank, resting when in use upon a support immediately behind the workman. The nail machine consists essentially of a pair of cutting chisels or edges, which work perpendicularly, parallel to each other; a gauge, to determine the breadth of a nail; a pair of grips, into which at the time the wedge of iron falls, and where it is firmly held until the small horizontal hammer strikes it and produces the head, when it is dropped into a box beneath. Brads are not headed, but are simply cut out of each other; that is to say, a deficiency in the parallelism of the cutting edge produces the head and prepares for the head of the next brad to be cut therefrom. Glaziers' brads being simple wedge-like pieces of iron, without any head whatever, are produced by the simple operations of the chisels or cutters.

When tacks are blued they are done in quantities by exposing them to heat in an oven or muffle, or upon an iron plate. Japanning is performed by the ordinary process.

NANKIN, is a peculiarly colored cotton cloth, originally manufactured in the above named ancient capital of China, from a native cotton of a brown yellow hue. Nankin cloth has been long imitated in perfection by our own manufacturers; and is now exported in considerable quantities from England to Canton. The following is the process for dyeing calico a nankin color.

1. Take 300 pounds of cotton yarn in hanks, being the quantity which four workmen can dye in a day. The yarn for the warp may be about No. 27's, and that for the weft 21's or 24's.

2. For *staining* that quantity, take 10 pounds of saturated alum, free from iron (see *MORDANT*); divide this into two portions; dissolve the first by itself in hot water, so as to form a solution, of spec. grav. 1° Baumé. The second portion is to be reserved for the *galling* bath.

3. *Galling*, is given with about 80 pounds of oak bark finely ground. This bark may serve for two quantities, if it be applied a little longer the second time.

4. Take 30 pounds of fresh slaked quicklime, and form with it a large bath of lime-water.

5. *Nitro-muriate of tin.* For the last bath, 10 or 12 pounds of solution of tin are used, which is prepared as follows:

Take 10 pounds of strong nitric acid, and dilute with pure water till its specific gravity be 26° B. Dissolve in it 4633 grains ($10\frac{1}{2}$ oz. avoird.) of sal ammoniac, and 3 oz. of nitre. Into this solvent, contained in a bottle set in cold water, introduce successively, in very small portions, 28 ounces of grain-tin granulated. This solution, when made, must be kept in a well stoppered bottle.

Three coppers are required, one round, about five feet in diameter, and 32 inches deep, for scouring the cotton; 2. two rectangular coppers tinned inside, each 5 feet long and 20 inches deep. Two boxes or cisterns of white wood are to be provided, the one for the lime-water bath, and the other for the solution of tin, each about 7 feet long, 32 inches wide, and 14 inches deep; they are set upon a platform 28 inches high. In the middle between these two chests, a plank is fixed, mounted with twenty-two pegs for wringing the hanks upon, as they are taken out of the bath.

6. *Aluming.* After the cotton yarn has been scoured with water, in the round copper, or being boiled in successive portions of 100 pounds, it must be winced in one of the square tinned coppers, containing two pounds of alum dissolved in 96 gallons of water, at a temperature of 165° F. It is to be then drained over the copper, exposed for some time upon the grass, rinsed in clear water, and wrung.

7. *The galling.* Having filled four-fifths of the second square copper with water, 40 pounds of ground oak bark are to be introduced, tied up in a bag of open canvass, and boiled for two hours. The bag being withdrawn, the cotton yarn is to be winced through the boiling tan bath for a quarter of an hour. While the yarn is set to drain above the bath, 28 ounces of alum are to be dissolved in it, and the yarn being once more winced through it for a quarter of an hour, is then taken out, drained, wrung, and exposed to the air. It has now acquired a deep but rather dull yellowish color, and is ready without washing for the next process. Bablah may be substituted for oak bark with advantage.

8. *The liming.* Into the cistern filled with fresh made lime-water, the hanks of cotton yarn, suspended upon a series of wooden rods, are to be dipped freely three times in rapid succession; then each hank is to be separately moved by hand through the lime bath, till the desired carmelite shade appear. A weak soda ley may be used instead of lime water.

9. *The brightening* is given by passing the above hanks, after squeezing, rinsing, and airing them, through a dilute bath of solution of tin. The color thus produced is said to resemble perfectly the nankin of China.

Another kind of nankin color is given by oxyde of iron, precipitated upon the fibre of the cloth, from a solution of the sulphate, by a solution of soda. See CALICO-PRINTING.

NAPHTHA, or ROCK-OIL (*Huile pétrole*, Fr.; *Steinöl*, Germ.); the Seneca oil of North America, is an ethereous or volatile oil, which is generated within the crust of the earth, and issues in many different localities. The colorless kind, called naphtha, occurs at Baku, near the Caspian Sea, where the vapors which it exhales are kindled, and the flame is applied to domestic and other economical purposes. Wells are also dug in that neighborhood, in which the naphtha is collected. Similar petroleum wells exist in the territory of the Birmans, at Yananghoung, upon the river Irawaddy, 80 hours' journey north-east of Pegu, where no less than 220 such springs issue from a pale blue clay, soaked with oil, which rests upon roofing slate. Under the slate is coal containing much pyrites. Each spring yields annually 173 casks of 950 pounds each. Petroleum is also found at Amiano in the duchy of Parma, at Saint Zibio in the grand duchy of Modena, at Neufchatel in Switzerland, at Clermont in France, upon some points of the banks of the Isar, at Gabian, a village near Beziers, at Tegernsee in Bavaria, at Val di Noto in Sicily, in Zante, Gallicia, Wallachia, Trinidad, Barbadoes, the United States, Rangoon, near Ava, &c. What is found in the market comes mostly from Trinidad. The city of Parma is lighted with naphtha.

The Persian rock-oil is colorless, limpid, very fluid, of a penetrating odor, a hot taste, and a specific gravity of 0.653; it is said to boil at 160° F. The common petroleum has a reddish-yellow color, which appears blue by reflected light, is transparent, has a spec. grav. of 0.836, and contains, according to Unverdorben, several oils of different degrees of volatility, a little oleine and stearine, resin, with a brown indifferent substance held in solution. By repeated rectifications its density may be reduced to 0.758 at 60° F. Native naphtha of specific gravity 0.749, is said by some to boil at 201° F. The condensed vapor consists of 85.05 carbon, and 14.30 hydrogen.

The naphtha procured by distilling the coal oil of the gas works, is of specific gravity 0.867, boils at 316° F., and consists of, carbon 85.04, hydrogen 12.31, and oxygen 4.65, by my experiments.

Rock-oil is very inflammable; its vapor forms with oxygen gas a mixture which vio-

lently detonates, and produces water and carbonic acid gas. It does not unite with water, but it imparts a peculiar smell and taste to it; it combines in all proportions with strong alcohol, with ether and oils, both essential and unctuous; it dissolves sulphur, phosphorus, iodine, camphor, most of the resins, wax, fats, and softens caoutchouc into a glairy varnish. When adulterated with oil of turpentine, it becomes thick and reddish brown, on being agitated in contact with strong sulphuric acid. A very fine black pigment may be prepared from the soot of petroleum lamps.

NAPHTHA AND ITS USES.—In the *Pharm. Journal* for July, 1848, a notice was inserted about the curative virtue of mineral naphtha in Asiatic cholera, as verified by Dr. Andreosky, physician to the commander-in-chief of the Russian army in Circassia. The naphtha there employed has been long known as the produce of springs on the north-west coast of the Caspian Sea, not far from the town of Derbend, near the Gulf of Baku, which was incorrectly printed Beker. It is surprising that in the instructions of the Petersburg police board just published, as to the proper precautions and best remedies against cholera, then beginning its ravages in that capital, no allusion whatever was made to naphtha, or to Dr. Andreosky's testimony in its favor. Are we hence to infer that the preceding recommendation of that substance is apocryphal, or that it has since lost all credit with the Russian faculty, by whom the police bulletin was prepared?

The soil near Derbent, from which the naphtha oozes into wells about thirty inches deep, is a clay marl, which is thoroughly soaked with that fluid. It has a pale yellow color, like that of Amiano near Parma, in Italy, but has a specific gravity of 0.853, while that of Amiano is only 0.836. Their boiling point is about 305° Fahr. Submitted to distillation, it affords a colorless fluid of spec. grav. 0.728, which boils at about 176° Fahr., but has acquired an empyreumatic odor, very different from that of the native product. Barbadoes tar of the best kind differs from these naphthas only in containing a little more bitumen, but it is equally fragrant. When distilled it yields a similar lighter naphtha, but likewise empyreumatic. The native substances are composed of 6 atoms of carbon and 6 atoms of hydrogen; or in 100 parts, of 86 and 14, by Hess's analysis.

Mineral petroleum seems to be very different in constitution and qualities from the fetid, factitious tar, derived from the igneous decomposition of pit-coal. The latter, according to Mr. Mansfield, is resolvable into six different substances, which he names *alliole*, *benzole*, *toluole*, *camphole*, *mortuole*, and *nitro-benzole*. I do not believe that a series of similar bodies can be extracted from native bitumen or petroleum. Indeed, he himself informed me that the fluid bitumen at one time pumped up abundantly from the Redding coalmines in Derbyshire, of which I furnished him with a specimen, afforded no such distinction of products, a result in accordance with my own experience. These differences between the natural and factitious petroleum lead me to conclude that the former are not the result of igneous action, but of that of water upon carbonaceous matter in the mineral strata. In confirmation of which view it may be observed, that not only in the above-named localities, but also at Monte Ciario near Piacenza, at the Lake of Tegern in Bavaria, near Neufchatel in Switzerland, in the Department of the Ain in France, &c., the bitumen is accompanied with a copious flow of water, on which it floats, and from which it is skimmed.

Petroleum of various shades, from the green of the Barbadoes springs to the pale yellow of Amiano, has been long known to possess certain medicinal properties. The rock-oil of Barbadoes, or as it has been vulgarly but improperly called, Barbadoes-tar, has been found an useful stimulant to torpid bowels, promoting in such a temperament the alvine discharge. Its chief value, however, is as an external remedy in a variety of cutaneous affections. But petroleum, either by itself, or combined with any of its solvent essential oils or spirits, would in general act rather as an irritant and rubefacient upon the skin in such cases, than as a purifying, cleansing, and soothing application. In this dilemma the idea occurred of incorporating the green rock-oil with fine curd soap. Thus a truly balsamic compound has been obtained. When the soap, used with water in the usual way, has cleared out the cutaneous pores, a film of the petroleum is deposited in them, powerfully remedial in many of the morbid affections of the skin. Such petrolized soap has been found to be quite a specific in the prickly heat of tropical regions, and of equal efficacy in the fiery eruptions incident to many persons in temperate climates. Hitherto, no method had been devised for modifying efficaciously the alkalinity of soap, which being, as in the best white curd article, a definite saline compound of stearic acid, and soda in its most caustic condition to the extent of six per cent., cannot fail to excoriate delicate skins. By the present happy invention, each particle of that salt is enveloped with a film of balsam, which mitigates its irritant, without interfering with its detergent quality. Hence we may account for the preference given to the petroline soap by all who habitually use it at the toilet-table.—*Pharm. Journ.* vol. viii. No. 2.

NAPHTHALINE is a peculiar white crystallizable substance, which may be

extracted by distillation from coal tar. It has a pungent aromatic smell and taste, and a specific gravity of 1.048. It is a solid bicarburet of hydrogen, consisting, by my experiments, of 92.9 of carbon, and 7.1 of hydrogen. It has not been applied to any use.

NAPLES YELLOW (*Jaune minéral*, Fr.; *Neapelgelb*, Germ.); is a fine yellow pigment called *giallolino*, in Italy, where it has been long prepared by a secret process; for few of the receipts which have been published produce a good color. It is employed not only in oil painting, but also for porcelain and enamel. It has a fresh, brilliant, rich hue, but is apt to be very unequal in different samples.

The following prescription has been confidently recommended. Twelve parts of metallic antimony are to be calcined in a reverberatory furnace, along with eight parts of red lead, and four parts of oxide of zinc. These mixed oxides being well rubbed together are to be fused; and the fused mass is to be triturated and elutriated into a fine powder. Chromate of lead has in a great measure superseded Naples yellow.

NATRON is the name of the native sesquicarbonate of soda, which occurs in Egypt, in the west of the Delta; also in the neighborhood of Fessan, in the province of Sukena in Northern Africa, where it exists under the name of *Trona*, crystallized along with sulphate of soda; near Symrna, in Tartary, Siberia, Hungary, Hindostan, and Mexico. In the last country, there are several natron lakes, a little to the north of Zucatecas, as well as in many other provinces. In Columbia, 48 miles from Merida, native mineral natron is dug up from the bottom of lakes in large quantities, under the name of *Urao*.

According to Laugier, the Egyptian natron consists of carbonate of soda 22.44, sulphate of soda 18.35, muriate of soda 38.64, water 14.0, insoluble matter 6.0. *Trona* is composed of carbonate of soda 65.75, sulphate of soda 7.65, muriate of soda 2.63, water 24, insoluble matter 1. The sesquicarbonate may be artificially prepared by boiling for a short time a solution of the bicarbonate.

NEALING. See **ANNEALING**.

NEB-NEB is the East Indian name of Bablah.

NEEDLE MANUFACTURE. When we consider the simplicity, smallness, and moderate price of a needle, we would be naturally led to suppose that this little instrument requires neither much labor nor complicated manipulations in its construction; but when we learn that every sewing needle, however inconsiderable its size, passes through the hands of 120 different operatives, before it is ready for sale, we cannot fail to be surprised.

The best steel, reduced by a wire-drawing machine to the suitable diameter, is the material of which needles are formed. It is brought in bundles to the needle factory, and carefully examined. For this purpose, the ends of a few wires in each bundle are cut off, ignited, and hardened by plunging them into cold water. They are now snapped between the fingers, in order to judge of their quality; the bundles belonging to the most brittle wires are set aside, to be employed in making a peculiar kind of needles.

After the quality of the steel wire has been properly ascertained, it is calibred by means of a gauge, to see if it be equally thick and round throughout, for which purpose merely some of the coils of the bundle of wires are tried. Those that are too thick are returned to the wire-drawer, or set apart for another size of needles.

The first operation, properly speaking, of the needle factory, is unwinding the bundles of wires. With this view the operative places the coil upon a somewhat conical reel, *fig. 750*, whereon he may fix it at a height proportioned to its diameter. The wire is wound off upon a wheel *n*, formed of eight equal arms, placed at equal distances round a nave, which is supported by a polished round axle of iron, made fast to a strong upright *c*, fixed to the floor of the workshop. Each of the arms is 54 inches long; and one of them *n*, consists of two parts; of an upper part, which bears the cross bar *z*, to which the wire is applied; and of an under part, connected with the nave. The part *z* slides in a slot in the fixed part *r*, and is made fast to it by a peg at a proper height for placing the ends of all the spokes in the circumference of a circle. This arrangement is necessary, to permit the wire to be readily taken off the reel, after being wound tight round its eight branches. The peg is then removed, the branch pushed down, and the coil of wire released. *Fig. 993* shows the wheel in profile. It is driven by the winch-handle *a*.

The new made coil is cut in two points diametrically opposite, either by hand shears, of which one of the branches is fixed in a block by a bolt and a nut, as shown in *fig. 994*, or by means of the mechanical shears, represented in *fig. 995*. The crank *a* is moved by a hydraulic wheel, or steam power, and rises and falls alternately. The extremity of this crank enters into a mortise cut in the arm *b* of a bent lever *b a c*, and is made fast to it by a bolt. An iron rod *d r*, hinged at one of its extremities to the end of the arm *c*, and at the other to the tail of the shears or chisel *e*, forces it to open and shut alternately. The operative placed upon the floor under *r* presents the coil to the action of the shears, which cut it into two bundles, composed each of 60 or 100 wires, upwards of 3 feet long. The chisel strikes 21 blows in the minute.

These bundles are afterwards cut with the same shears into the desired needle lengths, these being regulated by the diameter. For this purpose the wires are put into a semi-cylinder of the proper length, with their ends at the bottom of it, and are all cut across by this gauge. The wires, thus cut, are deposited into a box placed alongside of the workman.

Two successive incisions are required to cut 100 wires, the third is lost; hence the shears, striking 21 blows in a minute, cut in 10 hours fully 400,000 ends of steel wire, which produce more than 800,000 needles. The wires thus cut are more or less bent, and require to be straightened. This operation is executed with great promptitude, by means of an appropriate instrument. In two strong iron rings *A B*, *fig. 996*, of which one is shown in front view at *C*, 5000 or 6000 wires, closely packed together, are put; and the bundle is placed upon a flat smooth bench *L M*, *fig. 999*, covered with a cast-iron plate *D E*, in which there are two grooves of sufficient depth for receiving the two ring bundles of wire, or two openings like the rule *r*, *fig. 999*, upon which is placed the open rule *r*, shown in front in *fig. 998* upon a greater scale. The two rings must be carefully set at the intervals of the rule. By making this rule come and go five or six times with such pressure upon the bundles of wires as causes it to turn upon its axis, all the wires are straightened almost instantaneously.

The construction of the machine, represented in *fig. 999*, may require explanation. It consists of a frame in the form of a table, of which *L M* is the top; the cast-iron plate *D E* is inserted solidly into it. Above the table, seen in *fig. 997* in plan, there are two uprights *C H*, to support the cross bar *A A*, which is held in forks cut out in the top of each of the two uprights. This cross bar *A A*, enters tightly into a mortise cut in the swing piece *N*, at the point *N*, where it is fixed by a strong pin, so that the horizontal traverse communicated to the cross bar *A A* affects at the same time the swing piece *N*. At the bottom of this piece is fixed, as shown in the figure, the open rule *r*, seen upon a greater scale in *fig. 998*.

When the workman wishes to introduce the bundle *n*, he raises, by means of two chains *i k*, *fig. 999*, and the lever *G O*, the swing piece and the cross bar. For this purpose he draws down the chain *i*; and when he has placed the bundle properly, so that the two rings enter into the groove *E D*, *fig. 997*, he allows the swing piece to fall back, so that the same rings enter the open clefts of the rule *r*; he then seizes one of the projecting arms of the cross bar *A*, alternately pulling and pushing it in the horizontal direction, whereby he effects, as already stated, the straightening of the wires.

The wires are now taken to the pointing-tools, which usually consist of about 30 grindstones arranged in two rows, driven by a water-wheel.

Each stone is about 18 in. in diameter, and 4 in. thick. As they revolve with great velocity and are liable to fly in pieces, they are partially encased by iron plates, having a proper slit in them to admit of the application of the wires. The workman seated in front

of the grindstone, seizes 50 or 60 wires between the thumb and forefinger of his right hand, and directs one end of the bundle to the stone. By means of a bit of stout leather called a thumb-piece, of which A, fig. 1000, represents the profile, and a the plan, the workman presses the wires, and turns them about with his forefinger, giving them such a rotatory motion as to make their points conical. This operation, which is called *roughing down*, is dry grinding; because, if water were

made use of, the points of the needles would be rapidly rusted. It has been observed long ago, that the silicious and steel dust thrown off by the stones, was injurious to the eyes and lungs of the grinders; and many methods have been proposed for preventing its bad effects. The machine invented for this purpose by Mr. Prior, for which the Society of Arts voted a premium, deserves to be generally known.

A A, fig. 1001, is the fly-wheel of an ordinary lathe, round which the endless cord B B passes, and embraces the pulley C, mounted upon the axle of the grindstone D. The fly-wheel is supported by a strong frame E E, and may be turned by a winch-handle, as usual, or by mechanical power. In the needle factories, the pointing-shops are in general very large, and contain several grindstones running on the same long horizontal shaft, placed near the floor of the apartment, and driven by water or steam power. One of the extremities of the shaft of the wheel A has a kneed or bent winch F, which by means of an intermediate crank G G, sets in action a double bellows H I, with a continuous blast, consisting of the air feeder H below, and the air regulator I above. The first is composed of two flaps, one of them, a a, being fast and attached to the floor, and the other, e e, moving with a hinge-joint; both being joined by strong leather nailed to their edges. This flap has a tail g, of which the end is forked to receive the end of the crank G. Both flaps are perforated with openings furnished with valves for the admission of the air, which is thence driven into a horizontal pipe K, placed beneath the floor of the workshop, and may be afterwards directed in an uninterrupted blast upon the grindstone, by means of the tin tubes N O O, which embrace it, and have longitudinal slits in them. A brass socket is supposed to be fixed upon the ground; it communicates with the pipe K, by means of a small copper tube, into which one of the extremities of the pipe N is fitted; the other is supported by the point of a screw Q, and moves round it as a pivot, so as to allow the two upright branches O O, to be placed at the same distance from the grindstone. These branches are soldered to the horizontal pipe N, and connected at their top by the tube P.

The wind which escapes through the slits of these pipes, blows upon the grindstone, and carries off its dust into a conduit R, fig. 1001, which may be extended to S, beyond the wall of the building, or bent at right angles, as at T, to receive the conduits of the other grindstones of the factory.

A safety valve J, placed in an orifice formed in the regulator flap I, is kept shut by a

spiral spring of strong iron wire. It opens to allow the superfluous air to escape, when, by the rising of the bellows, the tail *x* presses upon a small piece of wood, and thereby prevents their being injured.

The wires thus pointed at both ends are transferred to the first workshop, and cut in two, to form two needles, so that all of one quality may be of equal length. For each sort a small instrument, *fig.* 1002, is employed, being a copper plate nearly square, having a turned up edge only upon two of its sides; the one of which is intended to receive all the points, and the other to resist the pressure of the shears. In this small tool a certain number of wires are put with their points in contact with the border, and they are cut together flush with the plate by means of the shears, *fig.* 994, which are moved by the knee of the workman. The remainder of the wires are then laid upon the same copper or brass tool, and are cut also even; there being a trifling waste in this operation. The pieces of wire out of which two needles are formed, are always left a little too long, as the pointer can never hit exact uniformity in his work.

These pointed wires are laid parallel to each other in little wooden boxes, and transferred to the head-flattener. This workman, seated at a table with a block of steel before him, about 3 inches cube, seizes in his left hand 20 or 25 needles, between his finger and thumb, spreading them out like a fan, with the points under the thumb, and the heads projecting; he lays these heads upon the steel block, and with a small flat-faced hammer strikes successive blows upon all the heads, so as to flatten each in an instant. He then arranges them in a box with the points turned the same way.

The flatted heads have become hardened by the blow of the hammer; when annealed by heating and slow cooling, they are handed to the *piercer*. This is commonly a child, who laying the head upon a block of steel, and applying the point of a small punch to it, pierces the eye with a smart tap of a hammer, applied first upon the one side, and then exactly opposite upon the other.

Another child trims the eyes, which he does by laying the needle upon a lump of lead, and driving a proper punch through its eye; then laying it sidewise upon a flat piece of steel, with the punch sticking in it, he gives it a tap on each side with his hammer, and causes the eye to take the shape of the punch. The operation of piercing and trimming the eyes, is performed by clever children with astonishing rapidity; who become so dexterous as to pierce with their punch a human hair, and thread it with another, for the amusement of visitors.

The next operative makes the groove at the eye, and rounds the head. He fixes the needle in pincers, *fig.* 1003, so that the eye corresponds to their flat side; he then rests the head of the needle in an angular groove, cut in a piece of hard wood fixed in a vice, with the eye in an upright position. He now forms the groove with a single stroke of a small file, dexterously applied, first to the one side of the needle, and then to the other. He next rounds and smooths the head with a small flat file. Having finished, he opens the pincers, throws the needle upon the bench, and puts another in its place. A still more expeditious method of making the grooves and finishing the heads has been long used in most English factories. A small ram is so mounted as to be made to rise and fall by a pedal lever, so that the child works the tool with his foot; in the same way as the heads of pins are fixed. A small die of tempered steel bears the form of the one channel or groove, another similar die, that of the other, both being in relief; these being worked by the lever pedal, finish the grooving of the eye at a single blow, by striking against each other, with the head of the needle between them.

The whole of the needles thus prepared are thrown pell-mell into a sort of drawer or box, in which they are, by a few dexterous jerks of the workman's hand, made to arrange themselves parallel to each other.

The needles are now ready for the tempering; for which purpose they are weighed out in quantities of about 30 pounds, which contain from 250,000 to 500,000 needles, and are carried in boxes to the *temperer*. He arranges these upon sheet-iron plates, about 10 inches long, and 5 inches broad, having borders only upon the two longer sides. These plates are heated in a proper furnace to bright redness for the larger needles, and to a less intense degree for the smaller; they are taken out, and inverted smartly over a cistern of water, so that all the needles may be immersed at the same moment, yet distinct from one another. The water being run off from the cistern, the needles are removed, and arranged by agitation in a box, as above described. Instead of heating the needles in a furnace, some manufacturers heat them by means of a bath of melted lead in a state of ignition.

After being suddenly plunged in the cold water, they are very hard and excessively brittle. The following mode of tempering them is practised at Neustadt. The needles are thrown into a sort of frying-pan along with a quantity of grease. The pan being placed on the fire, the fatty matter soon inflames, and is allowed to burn out; the needles are now found to be sufficiently well tempered. They must, however, be re-adjusted upon the steel anvil, because many of them get twisted in the hardening and tempering.

Polishing is the longest and not the least expensive process in the needle manufacture. This is done upon bundles containing 500,000 needles; and the same machine, under the guidance of one man, polishes from 20 to 30 bundles at a time; either by water or steam power. The needles are milled up in casks along with some quartzose sand interspersed between their layers, and the mixture is besmeared with rape-seed oil. Fig. 1004 represents one of the rolls or packets of needles 12 inches long, strongly

bound with cords. These packets are exposed to the to-and-fro pressure of wooden tables, by which they are rolled about, with the effect of causing every needle in the bundle to rub against its fellow, and against the silicious matter, or emery, enclosed in the bag. Fig. 1005 represents an improved table for polishing the needles by attrition-bags. The lower table *x x* is moveable, whereas in the old constructions it was fixed; the table *c* has merely a vertical motion, of pressure upon the bundles, whereas formerly it had both a vertical and horizontal motion. Several bundles may obviously be polished at once in the present machine. The table *x x* may be of any length that is required, and from 24 to 27 inches broad; resting upon the wooden rollers *x, x, x*, placed at suitable distances, it receives a horizontal motion, either by hand or other convenient power; the packets of needles *a, a, a*, are laid upon it, and over them the tables *c, c, c*, which are lifted by means of the chains *x, x, x*, and the levers *l, l, l*, in order to allow the needles to be introduced or removed. The see-saw motion forces the *rouleaux* to turn upon their own axes, and thereby creates such attrition among their contents as to polish them. The workman has merely to distribute these rolls upon the table *x*, in a direction perpendicular to that in which the table moves; and whenever one of them gets displaced, he sets it right, lifting by the help of the chain the loaded table. The table makes about 20 horizontal double vibrations in the minute; whereby each bundle, running over 24 inches each time, passes through 40 feet per minute, or 800 yards in the hour.

Scouring by the cask. After being worked during 18 or 20 hours under the tables, the needles are taken out of the packets, and put into wooden bowls, where they are mixed with sawdust to absorb the black grease upon their surfaces. They are next introduced into a cask, fig. 1006, and a workman seizing the winch *r*, turns it round a little; he now puts in some more sawdust at the door, *a, b*, which is then shut by the clasps *g g*, and continues the rotation till the needles be quite clean and clear in their eyes; which he ascertains by taking out a sample of them from time to time.

Winnowing is the next process, by means of a mechanical ventilator similar to that by which corn is winnowed. The sawdust is blown away, and the grinding powder is separated from the needles, which remain apart clean and bright.

The needles are in the next place arranged in order, by being shaken, as above described, in a small somewhat concave iron tray. After being thus laid parallel to each other, they are shaken up against the end of the tray, and accumulated in a nearly upright position, so that they can be seized in a heap and removed in a body upon a pallet knife, with the help of the forefinger.

The preceding five operations, of making up the *rouleaux*, rolling them under the tables, scouring the needles in the cask, winnowing, and arranging them, are repeated

ten times in succession, in manufacturing the best articles; the only variation being in the first process. Originally the bundles of needles are formed with alternate layers of silicious schistus and needles; but after the seventh time, bran freed from flour by sifting is substituted for the schistus. The subsequent four processes are, however, repeated as described. It has been found in England, that emery powder mixed with quartz and

mica or pounded granite, is preferable to everything else for polishing needles at first by attrition in the bags; at the second and following operations, emery mixed with olive oil is used, up to the eighth and ninth, for which putty or oxyde of tin with oil is substituted for the emery; at the tenth the putty is used with very little oil; and lastly bran is employed to give a finish. In this mode of operating, the needles are *scoured* in the copper cask shown in elevation in *fig. 1007* and in section in *fig. 1008*. The inner surface of this cask is studded with points to increase the friction among the needles; and a quantity of hot soap suds is repeatedly introduced to wash them clean. The cask must be slowly turned upon its axis, for fear of injuring the mass of needles which it contains. They are finally dried in the wooden cask by attrition with sawdust; then wiped individually with a linen rag or soft leather; when the damaged ones are thrown aside.

Sorting of the needles. This operation is performed in a dry upper chamber, kept free from damp by proper stoves. Here all the points are first laid the same way; and the needles are then picked out from each other in the order of their polish. The sorting is effected with surprising facility. The workman places 2000 or 3000 needles in an iron ring, *fig. 1009*, two inches in diameter, and sets all their heads in one plane; then on looking carefully at their points, he easily recognises the broken ones; and by means of a small hook fixed in a wooden handle, *fig. 1010*, he lays hold of the broken needle, and turns it out. These defective needles pass into the hands of another workman, who points them anew upon a grindstone, and they form articles of inferior value. The needles which have got bent in the polishing must now be straightened. The whole are finally arranged exactly according to their lengths by the tact of the finger and thumb of the sorter.

The needles are divided into quantities for packing in blue papers, by putting into a small balance the equivalent weight of 100 needles, and so measuring them out without the trouble of counting them individually.

The *bluer* receives these packets, and taking 25 of their needles at a time between the forefinger and thumb, he presses their points against a very small hone-stone of compact micaceous schist, mounted in a little lathe, as shown in *fig. 1011*, he turns them briskly round, giving the points a bluish cast, while he polishes and improves them. This partial polish is in the direction of the axis; that of the rest of the needle is transverse, which distinguishes the boundaries of the two. The little hone-stone is not cylindrical, but quadrangular, so that it strikes successive blows with its corners upon the needles as it revolves, producing the effect of filing lengthwise. Whenever these angles seem to be blunted, they are set again by the *bluer*.

It is easy to distinguish good English needles from spurious imitations; because the former have their axis coincident with their points, which is readily observed by turning them round between the finger and thumb.

The construction of a needle requires, as already stated, about 120 operations; but they are rapidly and uninterruptedly successive. A child can *trim* the eyes of 4000 needles per hour.

When we survey a manufacture of this kind, we cannot fail to observe, that the diversity of operations which the needles undergo bears the impress of great mechanical refinement. In the arts, to divide labor, is to abridge it; to multiply operations, is to simplify them; and to attach an operative exclusively to one process, is to render him much more economical and productive.

NEROLI is the name given by perfumers to the essential oil of orange flowers. It is procured by distillation with water, in the same way as the other volatile oils. Since in distilling water from neroli, an aroma is obtained different from that of the orange-flower, it has been concluded that the distilled water of orange-flowers owes its scent to some principle different from an essential oil.

NET (*Filet, réseau, Fr.; Netz, Germ.*) is a textile fabric of knotted meshes, for catching fish, and other purposes. Each mesh should be so secured as to be incapable of enlargement or diminution. The French government offered in 1802 a prize of 10,000 francs to the person who should invent a machine for making nets upon automatic principles, and adjudged it to M. Buron, who presented his mechanical invention to the *Conservatoire des Arts et Métiers*. It does not appear, however, that this machine has accomplished the object in view; for no establishment was ever mounted to carry it into execution. Nets are usually made by the fishermen and their families during periods of leisure. The formation of a mesh is too simple a matter to require description in this Dictionary.

NEUTRALIZATION is the state produced when acid and alkaline matters are combined in such proportions that neither predominates, as evinced by the color of tincture of litmus and cabbage remaining unaffected by the combination.

NICARAGUA WOOD is the wood of the *Casalpinia echinata*, a tree which grows in Nicaragua. It is used with solution of tin as a mordant to dye a bright but fugitive red. It is an inferior sort of Brazil wood.

NICKEL is a metal rather sparingly found, and in few localities; being usually associated with cobalt. Native nickel occurs at Westerwald in the Erzgebirge, in Bohemia, combined with arsenic, under the significant name of *Kupfernickel*; with cobalt, iron, and copper, as *Arsenic-nickel*, in the Harz; at Riechelsdorf in Hesse; as an oxide, in *Nickelschwärze*; as a sulphuret of nickel in *Haarkies*; as a sulphuret and arseniate of nickel in *Nickelglanz*; and with sulphur and antimony in *Nickelspiess glanz* at Siegen. Nickel is always present in meteoric stones. *Kupfernickel* occurs in numerous external shapes; as reniform, globular, botroidal, arborescent, massive, and disseminated; fracture, coarse or fine grained, with metallic lustre; color, copper red, occasionally brown and gray; in silver and cobalt veins, in gneiss, sienite, mica-slate, kupfer-schiefer, accompanied by speisse cobalt, native silver, quartz, &c. It is found in Westphalia near Olpe, in Hesse at Riechelsdorf, and Biber, in Baden; in the Saxon Erzgebirge near Schneeberg, and Freiberg; in Bohemia, at Joachimsthal; in Thuringia, at Saalfeld; in Steyermark near Schladming; in Hungary, France, and England.

Since the manufacture of German silver, or *Argentane*, became an object of commercial importance, the extraction of nickel has been undertaken upon a considerable scale. The cobalt ores are its most fruitful sources, and they are now treated by the method of Wöhler, to effect the separation of the two metals. The arsenic is expelled by roasting the powdered speise, first by itself, next with the addition of charcoal powder, till the garlic smell be no longer perceived. The residuum is to be mixed with three parts of sulphur and one of potash, melted in a crucible with a gentle heat, and the product being edulcorated with water, leaves a powder of metallic lustre, which is a sulphuret of nickel free from arsenic; while the arsenic associated with the sulphur, and combined with the resulting sulphuret of potassium, remains dissolved. Should any arsenic still be found in the sulphuret, as may happen if the first roasting heat was too great, the above process must be repeated. The sulphuret must be finally washed, dissolved in concentrated sulphuric acid, with the addition of a little nitric, the metal must be precipitated by a carbonated alkali, and the carbonate reduced with charcoal.

In operating upon kupfernickel, or speise, in which nickel predominates, after the arsenic, iron, and copper have been separated, ammonia is to be digested upon the mixed oxides of cobalt and nickel, which will dissolve them into a blue liquor. This being diluted with distilled water deprived of its air by boiling, is to be decomposed by caustic potash, till the blue color disappears, when the whole is to be put into a bottle tightly stoppered, and set aside to settle. The green precipitate of oxide of nickel, which slowly forms, being freed by decantation from the supernatant red solution of oxide of cobalt, is to be edulcorated and reduced to the metallic state in a crucible containing crown glass. Pure nickel in the form of a metallic powder is readily obtained by exposing its oxalate to modern ignition.

The reduction of the oxide of nickel with charcoal requires the heat of a powerful air furnace or smith's forge.

Nickel possesses a fine silver white color and lustre; it is hard, but malleable, both hot and cold; may be drawn into wire $\frac{1}{30}$ of an inch, and rolled into plates $\frac{1}{800}$ of an inch thick. A small quantity of arsenic destroys its ductility. When fused it has a specific gravity of 8.279, and when hammered, of 8.66 or 8.82; it is susceptible of magnetism, in a somewhat inferior degree to iron, but superior to cobalt. Mariners' compasses may be made of it. Its melting point is nearly as high as that of manganese. It is not oxydized by contact of air, but may be burned in oxygen gas.

There is one oxide and two suroxides of nickel. The oxide is of an ash-gray color, and is obtained by precipitation with an alkali from the solution of the muriate or nitrate. The niccolous suroxide of Berzelius is black, and may be procured by exposing the nitrate to a heat under redness. The niccolic suroxide has a dirty pale green color; but its identity is doubtful.

Nickel may be detected by cyanide of potassium in an acid solution of it and cobalt; the cyanide being added until the precipitate first formed is redissolved: dilute sulphuric acid is then added, and the mixture warmed and allowed to stand. A precipitate appearing shows the presence of nickel, whether it be cobalt cyanide, or simple cyanide of nickel.

Nickel (analyses of), by H. Rose. Nickel and cobalt are almost always associated together, and are very difficult to separate.

Upon the fact that in a solution of oxide of cobalt containing free muriatic acid, the whole of the metal is converted into the superoxide, by means of chlorine, while the chloride of nickel remains unaltered in the acid solution, Mr. H. Rose based a successful method for the separation of the metals. His method is as follows:—Both metals are dissolved in hydrochloric acid; the solution must contain a sufficient excess of free acid; it is then diluted with much water; if 1 or 2 grammes of the oxide are operated on, about 2 lbs. of water are added to the solution. As cobalt possesses a much greater coloring power than nickel, not only in fluxes but also in solutions, the diluted solution is of a rose color, even when the quantity of nickel present greatly exceeds that of the cobalt. A current of chlorine gas is then passed through the solution for several hours; the fluid must be thoroughly saturated with it, and the upper part of the flask above the liquid must remain filled with the gas after the current has ceased. Carbonate of baryta in excess is then added, and the whole allowed to stand for 12 or 18 hours, and frequently agitated. The precipitated superoxide of cobalt and the excess of carbonate of baryta are well washed with cold water, and dissolved in hot hydrochloric acid; after the separation of the baryta by sulphuric acid, the cobalt is precipitated by hydrate of potash, and after being washed and dried is reduced in a platinum or porcelain crucible by hydrogen gas. The fluid filtered from the superoxide of cobalt is of a pure green color. It is free from any trace of cobalt. After the removal of the baryta by means of sulphuric acid, the oxide of nickel is precipitated by caustic potash. Even this method did not give exact results on the first trial. 0.318 gr. metallic nickel and 0.602 gr. metallic cobalt were employed, and 0.430 gr. oxide of nickel and 0.580 gr. cobalt were obtained:—

		Employed.	Obtained.
Nickel	- - - - -	34.53	36.75
Cobalt	- - - - -	65.47	62.98
		100.00	99.73.

The cause of these incorrect results is, that the solution was filtered an hour or two after the precipitation of the superoxide of cobalt by the carbonate of baryta. It is necessary, however, to wait a considerable time, at least twelve hours, or even eighteen is better, and allow the excess of carbonate of baryta to remain in contact with the solution, as the superoxide of cobalt is precipitated very slowly: this explains the diminution of the cobalt and the increase of the nickel in the above experiment.

In another experiment, in which this source of error was avoided, 0.739 gr. metallic nickel and 0.540 metallic cobalt were used; and 0.548 gr. cobalt obtained, that is 42.84 per cent. instead of 42.22; the nickel was not determined. Two experiments were made by M. Weber. In one, 0.818 gr. cobalt, and 0.980 gr. nickel were taken, and 0.806 gr. cobalt and 1.274 oxide nickel obtained.

		Used.	Obtained.
Cobalt	- - - - -	45.50	44.77
Nickel	- - - - -	54.50	55.83
		100.00	100.60

In the second 0.516 gr. metallic cobalt and 0.637 oxide of nickel were taken, and 0.517 gr. cobalt obtained.

It will be seen from these experiments, that on the proper precautions being taken, very accurate results may be obtained by this method. It has also this advantage, that it is equally applicable whatever the relative proportions of the cobalt may be.

This or a similar method may be employed with advantage on a large scale, to procure cobalt and nickel in the purest state. Both metals are more employed in the arts than formerly; and in many cases it is important to prepare them as pure as possible. This

is the case when oxide of cobalt is to be employed in printing on porcelain, when a very small portion of nickel seriously affects the purity of the blue tint to be obtained by it. I have at least prepared the pure oxides of nickel and cobalt used in my laboratory in this manner; and in the experiments described above, none but the oxides so prepared were used. The nickel which occurs in commerce contains besides traces of arsenic, cobalt, copper and iron. It should be dissolved in hydrochloric acid, and the cobalt and iron separated by treatment with chlorine and carbonate of baryta, and then the copper precipitated by sulphuretted hydrogen.

It will be readily perceived, that not only cobalt, but also other metals, as iron and manganese, may be separated from nickel by this method. On the other hand, oxide of cobalt may be separated from the oxide of zinc, and other strongly basic oxides, which are not converted into superoxides. Nickel and cobalt can moreover be separated from metals to which they bear a close analogy in various ways. I have given a method in my "Manual of Analytical Chemistry," by which both these metals may be separated from manganese, viz., by converting them into chlorides, and treating these by hydrogen, which reduces the chlorides of nickel and cobalt to the metallic state, but not the chloride of manganese. This method affords accurate results, but is rather complicated. Völker has remarked, that at a very strong heat the chloride of manganese is slightly volatile. Although this is inappreciable except when the heat has been raised too high, still it is possible to effect their separation by simpler methods.

With many other chemists, I have convinced myself, that the method of Barresvil for the separation of the oxides of cobalt and manganese, by adding carbonate of baryta to the solution, and passing a current of sulphuretted hydrogen through it, is not applicable, since, as indeed might be seen *à priori*, not only the oxide of cobalt, but also the oxide of manganese, will be precipitated as a sulphuret.

From nickel, the manganese may be best separated in the same manner as cobalt, as I have remarked above. Manganese may be separated from both of them, however, by a method which, in its essential parts, was proposed by Wackenroder. It is based upon the fact, that although nickel and cobalt are not precipitated from their solutions by sulphuretted hydrogen, especially when they are slightly acid, still the sulphurets precipitated by hydrosulphate of ammonia are not dissolved by very dilute hydrochloric acid. I long ago, in the first edition of my "Manual of Analytical Chemistry," directed attention to this curious property, and made use of it for qualitative experiments, but at that time had not availed myself of it in quantitative separations. When the oxides are contained in an acid solution (which should not contain nitric acid however), it is made ammoniacal, and they are precipitated as sulphurets by hydrosulphate of ammonia. Very dilute hydrochloric acid is then added to the solution, until it has a very slightly acid reaction; the sulphurets of nickel and cobalt remain undissolved; they are washed with water containing a little sulphuretted hydrogen and a trace of hydrochloric acid. The sulphuret of manganese is dissolved with facility, but although the fluid filtered from the sulphurets of nickel and cobalt gives only a rather dirty flesh-colored precipitate on the addition of ammonia and hydrosulphate of ammonia, still the sulphuret of manganese contains small portions of sulphuret of cobalt or nickel; and when therefore it is treated anew with very dilute hydrochloric acid, minute quantities of the black sulphurets remain behind. By this repeated treatment, a very nearly correct separation may be obtained; but the results are more satisfactory in the separation of cobalt from manganese than of nickel from the latter metal, evidently because nickel is not very perfectly precipitated by hydrosulphate of ammonia: 0.300 gr. of metallic cobalt and 0.385 gr. of deutoxide of manganese gave—after the sulphuret had been converted by *aqua regia* into oxide, and this precipitated by hydrate of potash, and after the chloride of manganese dissolved was free from sulphuretted hydrogen and precipitated by carbonate of soda,—0.302 metallic cobalt and 0.392 oxide of manganese.

0.261 gr. of oxide of nickel, and 0.296 gr. oxide of manganese, treated in the same manner, gave 0.214 oxide of nickel and 324 oxide of manganese.

Iron also may be separated from nickel, and better still from cobalt, in the same manner as manganese, since sulphuret of iron, like sulphuret of manganese, is easily soluble in very dilute hydrochloric acid; but in this case the resolution of the sulphuret of iron is likewise necessary: 0.425 gr. metallic cobalt and 0.170 gr. sesquioxide of iron, when treated in this manner, gave 0.414 gr. metallic cobalt, and 0.172 sesquioxide of iron.

I have already stated, in the last edition of my "Manual of Analytical Chemistry," that the oxide of zinc may be completely precipitated from its solution in acetic acid by means of sulphuretted hydrogen when no strong inorganic acid is present, even though the solution contain a large excess of acetic acid; and recommended the separation of this oxide from alumina, the oxides of iron, manganese, and even from those of cobalt and nickel, by this method. This method also succeeds when a considerable addition of acetic acid is made to the solution, especially if the latter oxides are present.

From alumina oxide of nickel may be separated by fusing them together with hydrate of potash in a silver crucible; on treating the fused mass with water, the oxide of nickel remains behind in a dense state. It weighs rather more than the oxide employed, but contains no alumina, and potash must therefore be present. 0.238 gr. oxide of nickel mixed with alumina weighed, after it had been treated in this manner, 0.245 gr. By boiling with a solution of potash, nickel cannot be separated from alumina, when both are contained in a solution, not even when the treatment is repeated. When the 0.245 gr. was dissolved in hydrochloric acid with the help of a little sulphuric acid, and the separated solution of alumina in potash, to which more potash was added, mixed with the solution, and the whole boiled, the oxide of nickel separated weighed 0.320 gr. When this was dissolved in hydrochloric acid, a considerable quantity of alumina separated on the addition of ammonia in excess. As, however, the fusion of hydrate of potash in a silver crucible is attended with inconvenience, and the oxide of nickel obtained requires to be dissolved and precipitated anew, the separation of these oxides by means of carbonate of baryta is preferable.

I have tried in vain, by fusing with a fixed alkaline carbonate, to separate quantitatively alumina from the oxides of cobalt and nickel, and from those of other metals which are incapable of expelling the carbonic acid from an alkaline carbonate at an elevated temperature. It is difficult to obtain a perfectly clear solution by fusing alumina with carbonated alkali, and treating the melted mass with water; it is quickly rendered turbid by the carbonic acid of the atmosphere. A fused mass is much more easily obtained with carbonate of soda than with carbonate of potash.

Nickel and Cobalt.—Mingled with the beautiful samples of copper pyrites and argentiferous galena displayed in Class I. of the Great Exhibition, there were to be found several specimens of cobalt and nickel ores. These valuable articles lay buried beneath the huge bulk of their better known compeers, and, unless sought for, would fail to arrest the attention even of a scientific observer; thus singularly illustrating in the Crystal Palace the obscure position they occupy in the manufacturing industry of the nation. The art of working the ores of cobalt and nickel seems unknown in Great Britain, if we may judge by the fact, that though found in sufficient abundance, they are nowhere in this country converted into zaffre and speiss, the two primary marketable products elsewhere obtained from these ores. Although, therefore, no nation in the world consumes in its manufactures more cobalt and nickel than Great Britain, yet for these metals it is entirely dependent upon Norway, Northern Germany and the Netherlands; from whence we import annually not less than 400 tons of zaffre and smalts, and nearly the same quantity of nickel and speiss, to the conjoint value of about 150,000*l.* sterling. As these substances serve very different purposes in the arts, we propose to speak of them separately,—merely premising that cobalt forms the bases of all the blue colors seen on earthenware, whilst nickel is an indispensable ingredient in the various metallic alloys, known under the terms albat, German silver, &c. The specimens of ore previously alluded to as existing in the Great Exhibition have been derived from Cornwall, and contain, as is generally the case, both nickel and cobalt, thus far being precisely similar to the ores worked in Norway and Northern Germany. The foreign ores are, however, much richer than the Cornish, since these latter seldom contain more than from 2 to 7 per cent. of available metallic matter, whilst the former not unfrequently yield 12 or 15 per cent.; consequently, a process which answers quite well with the one may fail altogether, or prove profitless with the other; and this is exactly the whole secret of our national failure in working cobalt ore. The Swedish method has been tried in several parts of Cornwall, and has not in any one instance given a satisfactory result; hence, the Crystal Palace contains no specimen of British zaffre, and our potteries, glass works, and paper manufacturers procure from abroad that which ignorance and apathy deny them at home. In the German ore the quantity of metallic ingredients is not only larger than in the Cornish, but also of a more fusible character; consequently, when simply subjected to heat in a reverberatory furnace, the earthy and metallic elements separate of themselves by the mere disparity of their specific weights; and the silicious gangue, with a portion of oxide of iron, rises to the top; leaving a metallic compound of arsenic, cobalt, nickel, copper, and perhaps iron beneath. This latter, when carefully roasted in an oxidizing furnace, in contact with sand or ground flint, affords at once an impure silicate of cobalt and arseniuret of nickel,—two marketable products. The Cornish ores, from their metallic poverty, will not undergo the first fusion necessary to separate the silicious matrix of the mineral; and this trifling impediment seems actually to have benumbed the energy of that indomitable spirit of enterprise for which Britain is in most things justly celebrated. In the manufacture of iron, limestone is used to render the alumina and silica of the ore fusible; and without this no iron can be produced by the ordinary process. In roasting lead ore, lime cannot be dispensed with. In copper making, not only lime but also fluor spar is frequently needed; and the commonest cobalt ores of Cornwall clearly require nothing but a proper flux to afford

a compound of arsenic, cobalt and nickel, perfectly analogous to that procured from the German ore by mere fusion without a flux. The whole question, therefore, really resolves itself into the discovery of a cheap material capable of easy vitrification with the granitic matrix of the Cornwall ore, and which is nevertheless devoid of action upon the arseniuret of cobalt and nickel. The common fixed alkalis, though answering the first indication admirably, would not comply with the second condition; hence potash and soda, these great helpmates of industrial skill, are unfortunately excluded from the list of agents, as they act powerfully upon all the arseniurets, and would merely produce a worthless frit with the ore. Similar objections attach more or less to the alkaline earths, and therefore lime requires to be looked upon with suspicion. Borax would and does yield a satisfactory result, but its high price is an insurmountable obstacle. Fluor spar is of no avail, and bottle glass requires too strong a temperature, and to be used in too great a quantity, for economical application to a mineral already surcharged with extraneous matters.

These facts serve in some measure to explain, though we cannot in any way allow that they justify, the present condition of the zaffre market; since these very difficulties are daily overcome in one of the largest metallurgical operations carried on amongst us. Many of the ores of copper, when first received by the manufacturer, are in a state quite parallel to that of the Cornish ores of cobalt, even in regard to poverty of metal. There is the same excess of granitic matrix, the same necessity for avoiding the use of any agent capable of attacking sulphuret of copper, a substance possessing very similar chemical affinities to those of the arseniurets of nickel and cobalt. What then is the flux employed by the copper manufacturer in such cases? We reply at once,—it is the protoxide of iron which is formed from these poor copper ores by the action of heat, and combines with the silicate of the matrix so as to produce an extremely fusible silicate of iron, which permits the sulphuret of copper to fall down to the lower part of the reverberatory furnace, whilst the vitrified impurities of the ore are raked from its surface. Oxide of iron would most probably therefore enable a manufacturer, accustomed to furnace operations, to send into the market an arsenical compound of cobalt containing more than 50 per cent. of this metal, even if his interest failed to convince him of the great advantage resulting from its subsequent conversion into zaffre. Thus, then, the conditions of this seemingly difficult problem are answered, in a commercial sense; for oxide of iron is plentiful and cheap, its combination with silica is sufficiently fusible, and it has no action whatever upon metallic arseniurets. No doubt many other substances might be found equally applicable with the one we have mentioned; and, indeed, our object in thus dilating upon this and analogous topics is rather to stimulate inquiry than to lay down specific rules for practical guidance; consequently our remarks must be regarded at best as but a shadowy outline, the manufacturing details of which require careful filling in, to render the whole intelligible and useful.

Before quitting the subject of cobalt, it may be as well to advert to a particular ore of that metal, found near Keswick in Cumberland. This ore contains from two to three per cent. of cobalt, but is quite free from nickel,—a very unusual circumstance,—as even in meteoric stones cobalt is constantly accompanied by nickel, though this last metal not unfrequently exists without cobalt. As a coloring material, oxide of cobalt is seriously damaged by the presence of oxide of nickel, for these oxides produce colors almost complementary to each other; and therefore tending, by their admixture, to yield a neutral tint, as is observable when their saline solutions are united. The great advantage of working an ore of cobalt free from nickel must consequently be obvious to all. The Keswick mine is, nevertheless, almost abandoned at the present moment, through sheer inability to find a market for its produce; though for the finer kinds of porcelain and for enamel painting, the oxide of cobalt procured from it is worth fully a guinea per pound.

In the hope of drawing attention to a raw material at once so unique and valuable, we give the following original process for extracting pure oxide of cobalt from the Keswick cobalt ore:—Having carefully roasted a quantity of this ore, at a full red heat, in a muffle furnace, for two or three hours, it is next to be reduced to a fine powder, and then digested in muriatic acid of the specific gravity 1.10 or thereabout. And for this use the waste acid of the soda maker is well adapted, even though it may happen to contain arsenic and iron. After a few hours' digestion, the acidulous solution may be poured off and a fresh acid added, so as completely to exhaust the roasted ore, and dissolve all the metallic matter in it. Then mix the solution thus procured: and having thrown in a portion of powdered hematite or other form of peroxide of iron, evaporate the whole to dryness. Next pour boiling water on the dried mass, and stir in an excess of chalk, or finely powdered marble, and preserve the whole at a temperature of about 180° Fahr. until all evolution of carbonic acid ceases; then add

by of sulphate of soda, and throw the mixture on a filter, when a solution of chlo-

ride of cobalt will pass through, containing a small quantity of the sulphates of lime and soda, but altogether free from metallic contamination. This solution must now be super-saturated with a caustic lye of soda, and the mixture boiled for a few minutes in order to insure the rapid precipitation of the oxide of cobalt; which, after careful washing with hot water, is to be dried, and heated red hot, in a crucible, to give it the character suitable for the English market. One pound of Keswick ore will require about 8 ounces of muriatic acid, of the kind alluded to, with 2 ounces of hematite, 3 ounces of chalk, and the same quantity of salt cake or dry sulphate of soda. The explanation of this process is very simple: in the first instance, the metallic matters of the ore, consisting of iron, cobalt, arsenic, copper, and perhaps also lead, are dissolved by the muriatic acid; and, as all of these are precipitated by carbonate of lime, except cobalt, the chalk might now be added at once, but for the fact that the Keswick ore contains an excess of arsenic, which carries down a portion of cobalt in the state of arsenite of cobalt. To remedy this evil, peroxide of iron or hematite must be added, so as to ensure the existence of an excess of peroxide of iron in the solution; as this, on the introduction of the chalk, will unite to the arsenic, and thus prevent the precipitation of any cobalt at this stage of the operation. The cessation of all effervescence, indicates that the chalk has ceased to act, and that the iron, arsenic, copper, and lead are no longer in solution, but have been displaced by the lime of the chalk. To remove this lime, sulphate of soda is employed, since this throws down nearly the whole of the lime in the state of sulphate; after which caustic soda or potash will precipitate nothing from the filtered solution but pure oxide of cobalt. Although apparently somewhat complex in detail, this process is extremely simple and efficient in practice; and possesses, moreover, the advantage of being equally applicable to the treatment of speiss or arseniuret of nickel, from which pure oxide of nickel may be easily procured,—using, however, much more hematite than the quantity above indicated, in consequence of the absence of iron in speiss. From this latter circumstance, it must be obvious, that cobalt and nickel cannot be separated in the way just described; for, as has been stated, they both remain in solution after the employment of the chalk; and, indeed, no process has yet been published by which a perfect separation of these two metals can be effected. Ordinary Swedish zaffre contains, on an average, 15 per cent. of oxide of cobalt, mixed with about 3 per cent. of oxide of nickel; which latter seriously impairs the coloring power of zaffre. Hence it is that we have entered thus fully into this question; for as it is almost impossible to purify cobalt when contaminated with nickel, it is a kind of national disgrace to Great Britain that, having a pure ore of cobalt in the very centre of the island, our manufactures are unable either to compete with, or so much as contest for, the palm of superiority in the formation of zaffre.

NICOTIANINE, is the name of an oil recently extracted from the leaves of tobacco, which possesses the smell of tobacco smoke.

NICOTINE, is a peculiar principle, obtainable from the leaves and seeds of tobacco (*nicotiana tabacum*), by infusing them in acidulous water, evaporating the infusion to a certain point, adding lime to it, distilling, and treating the product which comes over with ether. It is colorless, has an acrimonious taste, a pungent smell, remains liquid at 30° Fahr., mixes in all proportions with water, but is in a great measure separable from it by ether, which dissolves it abundantly. It combines with acids, and forms salts acid and pungent like itself; the phosphate, oxalate, and tartrate being crystallizable. Nicotine causes the pupils to contract. A single drop of it is sufficient to kill a dog.

Macerate powdered tobacco for twenty-four hours in water acidulated with sulphuric acid; express the liquor, evaporate to the consistence of syrup, and distil the residue with a sufficient quantity of potash; add more water from time to time to prevent the decomposition of the nicotina, in consequence of the potash being too much concentrated. From this distillation a quantity of nicotina and ammonia will be obtained in the receiver, and these are to be neutralized with oxalic acid. Evaporate now to dryness, and treat the residue with boiling alcohol, which will dissolve the oxalate of nicotina, leaving the oxalate of ammonia unacted upon. Heat the oxalate of nicotina in solution of potash, and separate the nicotina with ether, in which it is soluble, and from which the ether may again be separated by distillation.

M. Ortigosa considers this nicotina not to be perfectly pure, but to contain a portion of water and of alcohol.

From the analysis of the salt formed by the combination of nicotina with the chlorides of platinum and mercury, M. Ortigosa has represented the composition of this vegetable principle by the following formula:

$$C_{10} = 73.26$$

$$H_8 = 9.65$$

$$Az_1 = 17.09$$

NITRATE OF AMMONIA, is prepared by neutralizing nitric acid with car-

bonate of ammonia, and crystallizing the solution. Heat converts it into water and laughing gas.

NITRATE OF LEAD (*Nitrate de plomb*, Fr.; *Salpetersaures bleioxyd*, Germ.); is made by saturating somewhat dilute nitric acid with oxide of lead (litharge) evaporating the neutral solution till a pellicle appears, and then exposing it in a hot chamber till it be converted into crystals, which are sometimes transparent, but generally opaque white octahedrons. Their spec. grav. is 4.068; they have a cooling, sweetish, pungent taste. They dissolve in 7 parts of cold, and in much less boiling water; they fuse at a moderate elevation of temperature, emit oxygen gas, and pass into oxide of lead. Their constituents are 67.3 oxide and 32.7 acid. Nitrate of lead is much employed in the chrome yellow style of **CALICO PRINTING**; which see.

There are three other compounds of nitric acid and lead oxide; viz., the bi-basic, the tri-basic, and the se-basic; which contain respectively 2, 3, and 6 atoms of base to 1 of acid.

NITRATE OF POTASH, *Nitre, saltpetre*. (*Nitrate de potasse*, Fr.; *Salpetersaures kali*, Germ.) This salt occurs native as an efflorescence upon limestones, sandstones, marls, chalk, and caltuff; it forms a saline crust in caverns, as also upon the surface of the ground in certain places, especially where animal matters have been decomposed. Such caverns exist in Germany near Homburg (Burkardush); in Apulia upon the Adriatic sea (Pulo di Mofetta); in France; in the East Indies; in Ceylon, where 22 nitiferous caverns are mentioned; in North America, at Crooked River, Tennessee, Kentucky, and upon the Missouri; in Brazil, Teneriffe, and Africa. Nitre occurs as an efflorescence upon the ground in Arragon, Hungary, Podolia, Sicily, Egypt, Persia, Bengal, China, Arabia, North America, and South America. Several plants contain saltpetre; particularly borage, dill, tobacco, sunflowers, stalks of maize, beet-root, bugloss, parietaria, &c. It has not hitherto been found in animal substances.

The question has been frequently put; how is nitre annually reproduced upon the surface of limestones and the ground, after it has been removed by washing? It has been said, in reply, that as secondary limestones contain remains of animal matters, the oxygen of the atmosphere, absorbed in virtue of the porous structure, will combine with their azote to form nitric acid; whence nitrate of lime will result. Where potash is present in the ground, a nitrate of that base will be next formed. The generation of nitre is in all cases limited to a very small distance from the surface of porous stones; no further, indeed, than where atmospheric air and moisture can penetrate; and none is ever produced upon the surface of compact stones, such as marble and quartz, or of argillaceous minerals. Dr. John Davy and M. Longchamp have advanced an opinion, that the presence of azotized matter is not necessary for the generation of nitric acid or nitrous salts, but that the oxygen and azote of the atmosphere, when condensed by capillarity, will combine in such proportions as to form nitric acid, through the agency of moisture and of neutralizing bases, such as lime, magnesia, potash, or soda. They conceive that as spongy platina serves to combine oxygen and hydrogen into water, or the vapor of alcohol and oxygen into acetic acid, and as the peroxyde as well as the hydrate of iron, and argillaceous minerals, serve to generate ammonia from the oxygen of the air and the hydrogen of water; in like manner, porous limestones, through the agency of water, operate upon the constituents of the atmosphere to produce nitric acid, without the presence of animal matter. This opinion may certainly be maintained; for in India, Spain, and several other countries, at a distance from all habitations, immense quantities of saltpetre are reproduced in soils which have been washed the year before. But, on the other hand, it is known that the production of this salt may be greatly facilitated and increased by the admixture of animal offals with calcareous earths.

The spontaneous generation of nitre in Spain, Egypt, and especially in India, is sufficient to supply the wants of the whole world. There this salt is observed to form upon the surface of the ground in silky tufts, or even in slender prismatic crystals, particularly during the continuance of the hot weather that succeeds copious rains. These saline efflorescences, after being collected by rude besoms of broom, are lixiviated, allowed to settle, evaporated, and crystallized. In France, Germany, Sweden, Hungary, &c., vast quantities of nitrous salts are obtained by artificial arrangements called *nitrières*, or nitre-beds. Very little nitrate of potash, indeed, is obtained in the first place; but the nitrates of lime and magnesia, which being deliquescent, remain in the nitrous earths in a semi-liquid state. The operation of converting these salts into good nitre is often sufficiently complex, in consequence of the presence of several muriates, which are difficult to eliminate.

The following instructions have been given by the consulting committee of *poudres et salpêtres* in France, for the construction of their *nitrières artificielles*. The permeability of the materials to the atmospheric air, being found to be as indispensable as is the presence of a base to fix the nitric acid at the instant of its formation, the first measure

is to select a light friable earth, containing as much carbonate of lime or old mortar-rubbish as possible; and to interstratify it with beds of dung, five or six inches thick, till a considerable heap be raised in the shape of a truncated pyramid, which should be placed under an open shed, and kept moist by watering it from time to time. When the whole appears to be decomposed into a kind of mould, it is to be spread under sheds in layers of from two to three feet thick; which are to be watered occasionally with urine and the drainings of dunghills, taking care not to soak them too much, lest they should be rendered impermeable to the air, though they should be always damp enough to favor the absorption and mutual action of the atmospherical gases. Moist garden mould affords an example of the physical condition most favorable to nitre-beds. The compost should be turned over, and well mixed with the spade once at least in every fortnight, and the sides of the shed should be partially closed; for although air be essential, wind is injurious, by carrying off the acid vapors, instead of allowing them to rest incumbent upon, and combine with, the bases. The chemical reaction is slow and successive, and can be made effective only by keeping the agents and materials in a state of quiescence. The whole process lasts two years; but since organic matters would yield in the lixiviation several soluble substances detrimental to the extraction of saltpetre, they must not be added during the operations of the latter six months; nor must any thing except clear water be used for watering during this period; at the end of which the whole organic ingredients of the beds will be totally decomposed. Where dung is not sufficiently abundant for the above stratifications, a nitre-bed should be formed in a stable with friable earth, covered with a layer of litter; after four months the litter is to be lifted off, the earth is to be turned over, then another layer of fresh earth, 8 or 9 inches thick, is to be placed over it, and a layer of the old and fresh litter over all. At the end of other four months, this operation is to be repeated; and in the course of a year the whole is ready to be transferred into the regular nitre-beds under a shed, as above described. Such are the laborious and disagreeable processes practised by the peasants of Sweden, each of whom is bound by law to have a nitre-bed, and to furnish a certain quantity of nitre to the state every year. His *nitriary* commonly consists of a small hut built of boards, with a bottom of rammed clay, covered by a wooden floor, upon which is spread a mixture of ordinary earth with calcareous sand or marl and lixiviated wood-ashes. This mixture is watered with stable urine, and its surface is turned over once a week in summer, and once a fortnight in winter. In some countries, walls 2 or 3 feet thick, and 6 or 7 high, are raised with the nitrifying compost, interspersed with weeds and branches of trees, in order at once to bind them together, and to favor the circulation of air. These walls are thatched with straw; they are placed with one of their faces in the direction of the rains; and must be moistened with water not rich in animal matter. One side of the walls is upright and smooth; while the other is sloped or terraced, to favor the admission of humidity into their interior. The nitre eventually forms a copious efflorescence upon the smooth side, whence it may be easily scraped off.

M. Longchamp, convinced that organic matters are a useless expense, and not in the least essential to nitrification, proposes to establish nitre-beds where fuel and labor are cheapest, as amidst forests, choosing as dry and low a piece of ground as possible, laying them out upon a square space of about 1000 feet in each side, in the middle of which the graduation-house may be built, and alongside of it sheds for the evaporation furnaces and pans. Upon each of the four sides the *nitrifying* sheds are to be erected, 130 feet long by 30 feet wide, where the lixiviation would be carried on, and whence the water would be conducted in gutters to the graduation-house. The sheds are to be closed at the sides by walls of *pisé*, and covered with thatch. No substance is so favorable to nitrification as the natural stony concretion known under the name of lime-tuf. In Touraine, where it is used as a building stone, the saltpetre makers re-establish the foundations of old houses at their own expense, provided they are allowed to carry off the old tuf, which owes its nitrifying properties not only to its chemical nature, but to its texture, which being of a homogeneous porosity, permits elastic fluids and vapors to pass through it freely in all directions. With the rough blocks of such tuf, walls about 20 inches thick, and moderately high, are to be raised, upon the principles above prescribed; in the absence of tuf, porous walls may be raised with a mixture of arable soil, sand, and mortar-rubbish, chalk or rich marl. The walls ought to be kept moist.

In France, the greater part of the indigenous saltpetre is obtained by lixiviating the mortar-rubbish of old buildings, especially of those upon the ground-floor, and in sunk cellars; which are by law reserved for this purpose. The first object of the manufacturer is then to ascertain the richness of his materials in nitrous salts, to see if they be worth the trouble of working; and this point he commonly determines merely by their saline, bitter, and pungent taste, though he might readily have recourse to the far surer criteria of lixiviation and evaporation. He next pounds them coarsely, and puts them into large casks open at top, and covered with straw at bottom; which are

placed in three successive levels. Water is poured into the casks till they are full, and after 12 hours' digestion it is run off, loaded with the salts, by a spigot near the bottom. A fresh quantity of water is then added, and drawn off after an interval of four hours; even a third and fourth lixiviation are had recourse to; but these weak liquors are reserved for lixiviating fresh rubbish. The contents of the casks upon the second and third lower levels are lixiviated with the liquors of the upper cask, till the leys indicate from 12 to 14 degrees of Baumé's hydrometer. They are now fit for evaporating to a greater density, and of then receiving the dose of wood-ashes requisite to convert the materials of lime and magnesia into nitrate of potash, with the precipitation of the carbonates of magnesia and lime. The solution of nitre is evaporated in a copper pan, and as it boils, the scum which rises to the surface must be diligently skimmed off into a cistern alongside. Muriate of soda being hardly more soluble in boiling than in cold water, separates during the concentration of the nitre, and is progressively removed with cullender-shaped ladles. The fire is withdrawn whenever the liquor has acquired the density of 80° B.; it is allowed to settle for a little while, and is then drawn off, by a lead syphon adjusted some way above the bottom, into iron vessels, to cool and crystallize. The crystals thus obtained are set to drain, then re-dissolved and re-crystallized. The further purification of nitre, is fully described under the article GUNPOWDER.

The annual production of saltpetre in France, by the above-described processes, during the wars of the Revolution, amounted to 2000 tons (2 millions of kilogrammes) of an article fit for the manufacture of gunpowder; of which seven twentieths were furnished by the saltpetre works of Paris alone. Considerably upwards of six times that quantity of common and cubic nitre were imported into the United Kingdom, for home consumption, during the year ending January 5, 1838.

Nitrate of potash crystallizes in six-sided prisms, with four narrow and two broad faces: the last being terminated by a dihedral summit, or two-sided acumination; they are striated lengthwise, and have fissures in their long axis, which are apt to contain mother water. The spec. gravity of nitre, varies from 1.93 to 2.00. It possesses a cooling, bitterish-pungent taste, is void of smell, permanent in the air when pure, fuses at a heat of about 662, into an oily-looking liquid, and concretes upon cooling into a solid mass, with a coarsely radiating fracture. This has got the unmeaning names of *sal-prunelle* and *mineral crystal*. At a red heat, nitre gives out at first a great deal of pretty pure oxygen gas; but afterwards nitrous acid fumes, while potash remains in the retort. It is soluble in 7 parts of water at 32°; in about 3½ at 60° F., in less than half a part at 194°, and in four tenths at 212°. It is very slightly soluble in spirit of wine, and not at all in absolute alcohol. It causes a powerful deflagration when thrown upon burning coals; and when a mixture of it with sulphur is thrown into a red-hot crucible, a very vivid light is emitted. Its constituents are, 46.55 potash, and 53.45 nitric acid.

Nitre is applied to many purposes:—1. to the manufacture of gunpowder; 2. to that of sulphuric acid; 3. to that of nitric acid, though nitrate of soda or cubic nitre has lately superseded this use of it to a considerable extent; 4. to that of flint-glass; 5. it is used in medicine; 6. for many chemical and pharmaceutical preparations; 7. for procuring by deflagration with charcoal or cream of tartar, pure carbonate of potash, as also black and white fluxes; 8. for mixing with salt in curing butcher meat; 9. in some countries for sprinkling in solution upon grain, to preserve it from insects; 10. for making fireworks. See FIRE-WORKS.

NITRATE OF SILVER (*Nitrate d'argent*, Fr.; *Silbersalpeter*, Germ.); is prepared by saturating pure nitric acid of specific grav. 1.25 with pure silver, evaporating the solution, and crystallizing the nitrate. When the drained crystals are fused in a platina capsule, and cast into slender cylinders in silver moulds, they constitute the *lunar caustic* of the surgeon. This should be white, and unchangeable by light. It is *deliquescent* in moist air. The crystals are colorless transparent 4 and 6 sided tables;

they possess a bitter, acrid, and most disagreeable metallic taste; they dissolve in their own weight of cold, and in much less of hot water; are soluble in four parts of boiling alcohol, but not in nitric acid; they deflagrate on redhot coals, like all the nitrates; and detonate with phosphorus when the two are struck together upon an anvil. They consist of 68.2 of oxyde, and 31.8 of acid. Nitrate of silver, when swallowed, is a very energetic poison; but it may be readily counteracted, by the administration of a dose of sea-salt, which converts the corrosive nitrate into the inert chloride of silver. Animal matter, immersed in a weak solution of neutral nitrate of silver, will keep unchanged for any length of time; and so will polished iron or steel. Nitrate of silver is such a delicate reagent of hydrochloric or muriatic acid, as to show by a sensible cloud, the presence of one 113 millionth part of it, or one 7 millionth part of sea-salt in distilled water. It is much used under the name of indelible ink, for writing upon linen with a pen; for which purpose one drachm of the fused salt should be dissolved in three quarters of an ounce of water, adding to the solution as much water of ammonia as will re-dissolve the precipitated oxyde, with sap-green to color it, and gum-water to make the volume amount to one ounce. Traces written with this liquid should be first heated before a fire to expel the excess of ammonia, and then exposed to the sun-beam to blacken. Another mode of using nitrate of silver as an indelible ink, is to imbue the linen first with solution of carbonate of soda, to dry the spot, and write upon it with a solution of nitrate of silver, thickened with gum, and tinted with sap-green.

NITRATE OF SODA, *Cubical Nitre* (*Nitrate de soude*, Fr.; *Würfelsalpeter*, Germ.), occurs under the nitre upon the lands in Spain, India, Chile, and remarkably in Peru, in the districts of Atacama and Taracapa, where it forms a bed several feet thick. It appears in several places upon the surface, and extends over a space of more than 40 leagues, approaching near to the frontiers of Chile. It is sometimes efflorescent, sometimes crystallized, but oftener confusedly mixed with clay and sand. This immensely valuable deposit is only three days' journey from the port of Conception in Chile, and from Iquique, another harbor situated in the southern part of Peru.

Nitrate of soda may be artificially prepared by neutralizing nitric acid with soda, and crystallizing the solution. It crystallizes in rhomboids, has a cooling, pungent, bitterish taste, less disagreeable than nitre; it becomes moist in the air; dissolves in 3 parts of water at 60° F., in less than 1 part of boiling water; deflagrates more slowly than nitre, and with an orange yellow flame. It consists, in its dry state of 36.6 soda and 63.4 nitric acid; but its crystals contain one prime equivalent of water; hence they are composed of, acid 56.84, base 33.68, water 9.47.

It is susceptible of the same applications as nitre, with the exception of making gun powder; for which it is not adapted, on account of its deliquescent property.

We extract the following from a paper read before the Royal Geographical Society of London, on the 28th of April, 1851, entitled *Observations on the Geography of Southern Peru*, &c. &c. by W. Bollaert, Esq. F. R. G. S.

"The existence of this valuable substance in the province of Tarapaca has been known in Europe about a century. In 1820, some of it was sent to England, but the duty then being so high, it was thrown overboard. In 1827, efforts were unsuccessfully made by an English house to export it. In 1830, a cargo was sent to the United States; it was found unsalable there, and a part of it taken to Liverpool, but was returned as unsalable in England. A cargo was then sent to France, and in 1831 another to England, when it became better known, and sold as high as 30s. to 40s. the cwt. Its price has varied very much; present quotations (1851) about 15s. Since 1831 to 1852, the exports of nitrate from Iquique have been 5,293,478 quintals, equal to about 239,860 tons, some of it being used as a fertilizer of land, some in the manufacture of nitric acid. The principal deposits of nitrate of soda, yet known, are found on the western side of the Pampa de Tamarugal, commencing immediately where the level plain ceases, and on the sides of some of the ravines running from the pampa towards the coast and in some of the hollows of the mountains. The nitrate has not been found nearer to the coast than 18 miles, and looks as if it gradually transferred itself into salt as it approached the coast. The officinos or refining works are divided into northern and southern Saladres; the old Saladres being about the centre of the former, and La Nueva Noria that of the latter; there are in all about 100 officinos. The nitrate deposits commence about Tilineche, and extend south near to Quillagua with interruptions of deposits of common salt. The nitrate caliche grounds vary in breadth; the average may be 100 yards, and in places 7 to 8 feet thick, and sometimes quite pure. In the ravines and hollows before mentioned, the nitrate is found on their shelving sides; the hollows look like dried-up cakes, and are covered with salt 2 to 3 feet thick, and on the margins there is nitrate of soda, oftentimes going down to some depth; in others there is a hard dry crust upon it, occasionally 4 feet thick. The nitrate caliche formed under this

crust is in thin layers, and so solid and pure as to be sought for, although the expense of blasting is very great.

"There are several varieties of the nitrate of soda calcule, the following being the principal.

"1. White, compact, containing 64 per cent.

"2. Yellow, occasioned by salts of iodine, 70 per cent.

"3. Gray compact, containing a little iron and a trace of iodine, 46 per cent.

"4. Gray crystalline, the most abundant variety, contains from 20 to 85 per cent., affording traces of iodine, with 1 to 8 per cent. of earthy matter.

"5. White crystalline: this resembles the refined nitrate.

"All these contain common salt, sulphate and carbonate of soda, muriate of lime, and occasionally some borate of lime, as found under the nitrate beds: one variety of the latter, composed of boracic acid 49.5, soda 8.8, water 26.0, lime 15.7=100, may probably become of use in this country in glass-making, &c.

"Fragments of shells have been noticed with and under the nitrate bed: this may account in some measure for the lime in the borate and muriate. Mr. Blake mentions that 200 feet above the Pampa (which is 3500 above the level of the sea), near to Los Saletres del porté, 'limestone containing shells rises from a bed consisting of pebbles and shells cemented together by salt and nitrate of soda; part of the shells are decomposed, whilst others are perfect in form, and like those now still found lying on the rocks in the inlets of the sea.'

"The rough nitrate of soda is broken into small pieces, put into boilers, water introduced, and the whole boiled; the nitrate is held in solution, while the earthy matter, salt, phosphates, &c., are separated and fall to the bottom of the vessel: the saturated solution of nitrate is let into a reservoir, where it deposits any remaining earthy matter; the clear liquor is run into shallow troughs, exposed to the sun, crystallization takes place, containing only 2 to 3 per cent. of impurities, and is ready to be conveyed to the coast for exportation. The Pampa de Tamarugal contains sufficient nitrate of soda for the consumption of Europe for ages; the desert of Atacama yields it; it has been met with on the Andes and in the Eastern plains.

NITRATE OF STRONTIA. (*Nitrate de Strontiane*, Fr.; *Salpetersäurer strontian*, Germ.) This salt is usually prepared from the sulphuret of strontium, obtained by decomposing sulphate of strontia with charcoal, by strong ignition of the mixed powders in a crucible. This sulphuret being treated with water, and the solution being filtered, is to be neutralized with nitric acid, as indicated by the test of turmeric paper; care being taken to avoid breathing the noxious sulphureted hydrogen gas, which is copiously disengaged. The neutral nitrate being properly evaporated and set aside, affords colorless, transparent, slender octahedral crystals. It has a cooling, yet somewhat acid taste; is soluble in 5 parts of cold, and in one half part of boiling water, as also in alcohol; is

permanent in the air, deflagrates upon burning coals, gives off oxygen when calcined, and leaves caustic strontia. The salt consists of 48.9 strontia and 51.1 nitric acid. That salt is anhydrous; but there is another variety of it, which contains nearly 40 per cent. of water of crystallization, which occurs in large octahedrons. This is preferred for fireworks, because by efflorescence it is easily obtained in a fine powder, which mixes more intimately with the chlorate of potash and charcoal, for the composition of the brilliant red fires, now so much admired in theatrical conflagrations.

NITRIC ACID, *Aqua fortis* (*Acide nitrique*, Fr.; *Salpetersäure*, Germ.), exists, in combination with the bases, potash, soda, lime, magnesia, in both the mineral and vegetable kingdoms. This acid is never found insulated. It was distilled from saltpetre so long ago as the 13th century, by igniting that salt, mixed with coppers or clay, in a retort. Nitric acid is generated when a mixture of oxygen and nitrogen gases, confined over water or an alkaline solution, has a series of electrical explosions passed through it. In this way the salubrious atmosphere may be converted into corrosive aqua fortis. When a little hydrogen is introduced into the mixed gases, standing over water, the chemical agency of the electricity becomes more intense, and the acid is more rapidly formed from its elements, with the production of some nitrate of ammonia.

Nitric acid is usually made on the small scale by distilling, with the heat of a sand-bath, a mixture of 3 parts of pure nitre, and 2 parts of strong sulphuric acid, in a large glass retort, connected by a long glass tube with a globular receiver surrounded by cold water. By a well-regulated distillation, a pure acid, of specific gravity 1.500, may be thus obtained, amounting in weight to about two thirds of the nitre employed. To obtain easily the whole nitric acid, equal weights of nitre and concentrated sulphuric acid may be taken; in which case but a moderate heat need be applied to the retort. The residuum will be bisulphate of potash. When only the single equivalent proportion of sulphuric acid is used, namely, 48 parts for 100 of nitre, a much higher heat is required to complete the distillation, whereby more or less of the nitric acid is decomposed, while a compact neutral sulphate of potash is left in the retort, very difficult to remove by solution in water, and therefore apt to destroy the vessel.

Aqua fortis is manufactured upon the great scale in iron pots or cylinders of the same construction as I have described under muriatic acid. The more concentrated the sulphuric acid is, the less corrosively will it act upon the metal; and it is commonly used in the proportion of one part by weight to two of nitre. The salt being introduced into the cool retort, and the lid being luted tight, the acid is to be slowly poured in through the aperture *f*, fig. 748; while the aperture *g* is connected by a long glass tube with a range of balloons inserted into each other, and laid upon a sloping bed of sand. The bottle *i*, with 3 tubulures partly filled with water, which is required for condensing muriatic acid gas, must, for the present purpose, be replaced by a series of empty receivers, either of glass or salt-glazed stoneware. The cylinders should be only half filled, and be worked off by a gradually raised heat.

Commercial aqua fortis is very generally contaminated with sulphuric and muriatic acids, as also with alkaline sulphates and muriates. The quantity of these salts may be readily ascertained by evaporating in a glass capsule a given weight of the aqua fortis; while that of the muriatic acid may be determined by nitrate of silver; and of sulphuric acid, by nitrate of baryta. Aqua fortis may be purified in a great measure, by re-distillation at a gentle heat; rejecting the first liquid which comes over, as it contains the chlorine impregnation; receiving the middle portion as genuine nitric acid; and leaving a residuum in the retort, as being contaminated with sulphuric acid.

Since nitrate of soda has been so abundantly imported into Europe from Peru, it has been employed by many manufacturers in preference to nitre for the extraction of nitric acid, because it is cheaper, and because the residuum of the distillation, being sulphate of soda, is more readily removed by solution from glass retorts, when a range of these set in a gallery furnace is the apparatus employed. Nitric acid of specific gravity 1.47 may be obtained colorless; but by further concentration a portion of it is decomposed whereby some nitrous acid is produced, which gives it a straw-yellow tinge. At this strength it exhales white or orange fumes, which have a peculiar, though not very disagreeable smell; and even when largely diluted with water, it tastes extremely sour. The greatest density at which it can be obtained is 1.51 or perhaps 1.52, at 60° F., in which state, or even when much weaker, it powerfully corrodes all animal, vegetable, and most metallic bodies. When slightly diluted it is applied, with many precautions, to silk and woollen stuffs, to stain them of a bright yellow hue. See CALICO-PRINTING, page 246.

In the dry state, as it exists in nitre, this acid consists of 26.15 parts by weight of azote, and 73.85 of oxygen; or of 2 volumes of the first gas, and 5 volumes of the second.

When of specific gravity 1.5, it boils at about 210° Fahr.; of 1.45, it boils at about 180°; of 1.42, it boils at 253°; and of 1.40, at 246° F. If an acid stronger than 1.420 be distilled in a retort, it gradually becomes weaker; and if weaker than 1.42, it gradually becomes stronger, till it assumes that standard density. Acid of specific gravity

1.485 has no more action upon tin than water has, though when either stronger or weaker it oxidizes it rapidly, and evolves fumes of nitrous gas with explosive violence. In my two papers upon nitric acid published in the fourth and sixth volumes of the *Journal of Science* (1818 and 1819), I investigated the chemical relations of these phenomena. Acid of 1.420 consists of 1 atom of dry acid, and 4 of water; acid of 1.485, of 1 atom of dry acid, and 2 of water; the latter compound possesses a stable equilibrium as to chemical agency; the former as to calorific. Acid of specific gravity 1.334, consisting of 7 atoms of water, and 1 of dry acid, resists the decomposing agency of light. Nitric acid acts with great energy upon most combustible substances, simple or compound, giving up oxygen to them, and resolving itself into nitrous gas, or even azote. Such is the result of its action upon hydrogen, phosphorus, sulphur, charcoal, sugar, gum, starch, silver, mercury, copper, iron, tin, and most other metals.

From muriatic to nitric acid the transmission is easy, though nitric acid is never obtained as the waste product of any chemical operation. Its manufacture is invariably the primary object of the process by which it is procured. The ordinary method consists in heating together, in a distillatory apparatus, a mixture of nitrate of soda or potash with sulphuric acid. In this way, the sulphuric acid unites with the soda or potash, as the case may be, forming commercial products, also salt cake and sal-enixen; whilst the nitric acid combines with the water of the sulphuric acid, and, passing away under the influence of the heat, is condensed in the receiver of the apparatus. A decomposition of this kind is sometimes denominated a simple decomposition; but in reality it is not so, as the transfer of the water completes the cycle of elective affinity.

It has been proposed, and even carried into practice, to decompose nitrate of soda by the action of boric acid, so as to produce borate of soda, or borax, and thus render the nitric acid a secondary product. The success of this process depends, however, upon a circumstance of a somewhat curious kind. Strong nitric acid is much more volatile than weak acid; and hence it is more easily expelled from its combination with soda in a concentrated than in a diluted form. Now, boric acid has 3 atoms of water in its crystallized condition; therefore, if we take 2 atoms of this acid, we have 6 atoms of water to unite with the 1 atom of nitric acid capable of being disengaged from nitrate of soda; whereas this quantity of nitric acid needs at most but 2 atoms. The secret, therefore, is to dry the boric acid in the first instance, so as to get rid of the surplus water; and this is easily done at a temperature of 212° Fahr., at which two-thirds of

the water readily leave the boracic acid, and thus afford a mono-hydrated compound, 2 atoms of which contain precisely the amount of water needed for one atom of nitric acid, and also of the boracic acid requisite for the production of the baborate of soda. There are some peculiarities connected with the application of the necessary temperature; but they are of less importance. The baborate of soda is afterwards dissolved in hot water, and crystallized. This process has been patented in France within the last few years, by a M. Mallet, of Paris. One of the most extensive uses of nitric acid, and for which, indeed, it is chiefly fabricated, is the manufacture of oxalic acid.

Nitric Acid, anhydrous.—By treating nitrate of silver with perfectly dry chlorine, M. Deville has succeeded in isolating anhydrous nitric acid, the existence of which was demonstrated by numerous analyses. This beautiful substance is obtained in colorless crystals, which are perfectly brilliant and limpid, and may be procured of considerable size; when they are slowly deposited in a current of gas rendered very cold, their edges are a centimetre in length. These crystals are prisms of 6 faces, which appear to be derived from a right prism with a rhombic base. They melt at a temperature not much exceeding 85.5 Fahr.; their boiling point is about 113°; and at 50° the tension of this substance is very considerable. In contact with water it becomes very hot, and dissolves in it without imparting color, and without disengaging any gas; it then produces with barytes the nitrate of that base. When heated, its decomposition appears to commence nearly at its boiling point. This circumstance is an obstacle to the determination of the density of its vapor by the process of M. Dumas.

The process by which M. Deville obtained anhydrous nitric acid is very simple; but the readiness with which it penetrates tubes of caoutchouc renders it necessary to unite all the pieces of the apparatus by melting them. The following is the process:—The author employs a U-shaped tube capable of containing 500 gr. of nitrate of silver dried in the apparatus at 356° Fahr. in a current of dry carbonic acid gas. Another very large U tube is connected with this, and to its lower part is attached a small spherical reservoir; it is in this reservoir that a liquid is deposited which always forms during the operation, and which is exclusively volatile (nitrous acid?). The tube containing the nitrate of silver is immersed in water covered with a thin stratum of oil, and heated by means of a spirit lamp communicating with a reservoir at a constant level. The chlorine issues from a glass gasometer, and its displacement is effected by a slow and constant flow of concentrated sulphuric acid. The chlorine must afterwards pass over chloride of lime, and then over pumice-stone moistened with sulphuric acid. At common temperatures no effect appears to be produced. The nitrate of silver must be heated to 203° Fahr., the temperature being then quickly reduced to 136° or 154°, but not lower. At the commencement, hyponitrous acid, distinguishable by its color and ready condensation, is produced; and when the temperature has reached its lowest point, the production of crystals begins, and they soon choke the receiver, cooled to 6° below zero; they are always deposited upon that part of the receiver which is not immersed in the freezing mixture, and M. Deville states that ice alone is sufficient to occasion their formation.

The gases are colored, and the small sphere of the cooled tube contains a small quantity of liquid, which must be taken from the apparatus before the nitric acid is removed to another vessel; this latter operation is readily effected by replacing the current of chlorine by one of carbonic acid. The condenser is then to be no longer cooled, and the vessel for receiving the crystals is to be immersed in a freezing mixture; this is fastened to the producing apparatus by means of a caoutchouc tube furnished with amianthus. The chlorine should pass very slowly at the rate of about 3 or 4 litres in 24 hours. All the gas, however, is not absorbed by the nitrate of silver. Oxygen is evolved, the volume of which appears to be equal to that of the chlorine employed. An apparatus thus constructed operates day and night without watching, care being however taken to renew the sulphuric acid which displaces the chlorine, the spirit of the lamp, and the ingredients of the freezing mixture.

The author states that he shall forward hereafter a more complete memoir, in which he will describe the chemical properties of the anhydrous nitric acid, and detail the results of his researches on the action of chlorine and hypochlorous acid on the salts of silver.

NITROGEN, DEUTOXYDE OF; *Nitrous gas, Nitric oxyde (Deutoxyde d'azote, Fr.; Stickstoffoxyd, Germ.)* is a gaseous body which may be obtained by pouring upon copper or mercury, in a retort, nitric acid of moderate strength. The nitrous gas comes over in abundance without the aid of heat, and may be received over water freed from air, or over mercury, in the pneumatic trough. It is elastic and colorless; what taste and smell it possesses are unknown, because the moment it is exposed to the mouth or nostrils, it absorbs atmospheric oxygen, and becomes nitrous or nitric acid. Its specific gravity is 1.0393, or 1.04; whence 100 cubic inches weigh 36.66 gr. Water condenses not more than $\frac{1}{25}$ of its volume of this gas. It extinguishes animal life, and the flame of many

combustibles; but of phosphorus well kindled, it brightens the flame in a most remarkable degree. It consists of 47 parts of nitrogen gas, and 53 of oxygen gas, by weight; and of equal parts in bulk, without any condensation; so that the specific gravity of the deutoxide of nitrogen is the arithmetical mean of the two constituents. The constitution of this gas, and the play of affinities which it exercises in the formation of sulphuric acid, are deeply interesting to the chemical manufacturer.

The *Hyponitrous acid* (*Salpetrigesäure*, Germ.), like the preceding compound, deserves notice here, on account of the part it plays in the conversion of sulphur into sulphuric acid, by the agency of nitre. It is formed by mingling four volumes of deutoxide of nitrogen with one volume of oxygen; and appears as a dark orange vapor, which is condensable into a liquid at a temperature of 40° below zero, Fahr. When distilled, this liquid leaves a dark yellow fluid. The pure hyponitrous acid consists of 37.12 nitrogen, and 62.88 oxygen; or of two volumes of the first, and three of the second. Water converts it into nitric acid and deutoxide of nitrogen; the latter of which escapes with effervescence. This acid oxidizes most combustible bodies with peculiar energy; and though its vapor does not operate upon dry sulphurous acid, yet, through the agency of steam, it converts it into sulphuric acid, itself being simultaneously transformed into deutoxide of nitrogen; ready to become hyponitrous acid again, and to perform a circulating series of important metamorphoses. See SULPHURIC ACID.

NITROGEN, PREPARATION OF. This process is founded on the decomposition of nitrate of ammonia, which, as is already known, is resolved into nitrogen and water under the influence of heat; but as this salt is difficult to prepare, I replace it by a mixture of an alkaline nitrate of potash and sal ammoniac, a mixture which contains the elements of nitrite of ammonia and chloride of potassium. The best method of obtaining the nitrite of potash in a convenient state is to pass nitrous acid gas, formed by the action of 10 parts of nitric acid on one part of starch, through a solution of caustic potash having a sp. gr. 1.38, until the solution acquires an acid reaction; and then to add a little caustic potash, so as to render it distinctly alkaline. As the solution thus prepared does not undergo alteration from keeping, it may be held in readiness; and when the nitrogen is required, it is only necessary to mix one volume of the above solution with three volumes of a concentrated solution of sal-ammoniac, and to heat the mixture in a flask. The disengagement of the gas takes place almost immediately, and continues with great regularity.

As it is necessary, in order to make the gas pure, that the nitrate should be alkaline, there will be a disengagement at the same time of a little ammonia, but this is of no consequence; if the nitrogen be required completely free from ammonia, it is sufficient to pass the gas through a vessel containing water acidulated with a little sulphuric acid.

The following are the experiments by which I have satisfied myself of the purity of the nitrogen thus obtained:—

1. After freeing the gas from ammonia as above described, it was conveyed into a tube containing a mixture of zinc, sulphuric acid, and water; into the presence, therefore, of nascent hydrogen. The experiment was continued for some time, and when concluded I could not detect a trace of ammonia in the solution.

The solution was also negative on testing it with sulphate of iron and dilute sulphuric acid.

2. I placed in a glass tube, such as is used for organic analysis, a determined quantity of copper recently reduced by hydrogen, and exposed this for half an hour to the action of a red heat and of a current of the nitrogen washed and subsequently dried by passing it through pumice-stone wetted with oil of vitriol; taking at the same time the precaution not to heat the tube until all the atmospheric air had been displaced by the nitrogen. This experiment was repeated several times, without any alteration being observed either in the exterior appearance of the copper or in its weight.

NITROGEN GAS, or AZOTE (Eng. and Fr.; *Stickstoffgas*, Germ.), constitutes about 79 hundredths of the bulk of the atmospheric air; it is copiously disengaged from several mineral springs, as from the natural basins of hot water which supply the baths of Leuk, near the Gemmi in Switzerland, and from other springs, in the Pyrenees, in Ceylon, South and North America, &c. It exists also in flesh and most animal substances, as well as in some vegetable products, being one of their essential constituents. When phosphorus is burnt within a jar filled with air, standing over water in the pneumatic trough, it consumes or absorbs the oxygen, and leaves nitrogen, which may be rendered pure by agitation with water. By exposing nitrite of ammonia to heat in a retort, nitrogen comes over alone in great abundance; for the hydrogen of the ammonia is sufficient to saturate the oxygen of the acid, and to convert it into water; while the nitrogen of both constituents is set at liberty. By transmitting chlorine through water of ammonia, or digesting lean flesh in warm nitric acid, nitrogen may also be obtained. This permanently elastic gas is destitute of color, taste, and smell; it has a specific gra-

vity of 0.976, air being 1.000. Hence 100 cubic inches of it weigh 29.7 gr. It extinguishes all burning bodies, and when respired without oxygen is fatal to animal life.

NITROGEN, PROTOXYDE OF, *Nitrous oxide* (*Protoxyde d'azote*, Fr.; *Stickstoffoxydul*, Germ.), is a gas which displays remarkable powers when breathed, causing in many persons unrestrainable feelings of exhilaration, whence it has been called the laughing or intoxicating gas. It is prepared by exposing crystallized nitrate of ammonia to a heat of about 350° Fahr. in a glass retort. It is much denser than the air of the atmosphere, having a spec. grav. of 1.527; whence 100 cubic inches weigh 46.6 grains. It consists of 63.64 parts of nitrogen, and 36.36 of oxygen, by weight; or of two volumes of nitrogen and one volume of oxygen, condensed by reciprocal attraction into two volumes. It is colorless, and possesses all the mechanical properties of the atmosphere. Water previously freed from air absorbs its own volume of this gas; and thus affords a ready criterion for estimating its freedom from incondensable gases, as oxygen, nitrogen, and its deutoxyde. Several combustibles burn in this gas with an enlarged blue and very vivid flame; and it relumes a taper which has been blown out, provided its tip be red-hot. By powerful pressure it may be liquefied. See GAS.

NITRO-MURIATIC ACID, *Aqua regia* (*Acide nitro-muriatique*, Fr.; *Salpeter salzsäure*, *Königswasser*, Germ.) is the compound menstruum invented by the alchemists for dissolving gold. If strong nitric acid, orange-colored by saturation with nitrous gas (deutoxyde of azote), be mixed with the strongest liquid muriatic acid, no other effect is produced than might be expected from the action of nitrous acid of the same strength upon an equal quantity of water; nor has the mixed acid so formed any power of acting upon gold or platina. But if colorless aquafortis and ordinary muriatic acid be mixed together, the mixture immediately becomes yellow, and acquires the power of dissolving these two noble metals. When gently heated, pure chlorine gas rises from it, and its color becomes deeper; when further heated, chlorine still rises, but now mixed with nitrous acid gas. If the process has been very long continued, till the color becomes very dark, no more chlorine can be procured, and the liquor has lost the power of dissolving gold. It then consists of nitrous and muriatic acids. It appears, therefore, that aqua regia owes its peculiar properties to the mutual decomposition of the nitric and muriatic acids; and that water, chlorine, and nitrous acid gas are the results of that reaction. Aqua regia does not, strictly speaking, oxydize gold and platinum; it causes merely their combination with chlorine. It may be composed of very different proportions of the two acids; the nitric being commonly of specific gravity 1.34; the muriatic, of specific gravity 1.18 or 1.19. Sometimes 3 parts, and at others 6 parts of the muriatic acid are mixed with 1 of nitric: and occasionally muriate of ammonia, instead of muriatic acid, is added to nitric acid for particular purposes, as for making a solution of tin for the dyers. An aqua regia may also be prepared by dissolving nitre in muriatic acid.

NITROUS ACID (*Acide nitreux*, Fr.; *Salpetrige salpetersäure*, Germ.) may be procured by distilling, in a coated glass retort, perfectly dry nitrate of lead, into a glass receiver surrounded with a freezing mixture. The acid passes over in vapor, and condenses into a liquid; oxygen gas escapes through the safety tube; while oxyde of lead remains in the bottom of the retort. Nitrous acid may also be obtained by distilling strong fuming nitric acid, at the lowest possible temperature, and rectifying what comes over. At 42° zero, Fahr., this acid is colorless; at 32° it is wax yellow; at 60° it has an orange hue. It possesses a strong smell, has a very pungent, acrid, sour taste, and a specific gravity of 1.42. It powerfully decomposes organic bodies, staining them yellow. It boils at 82° Fahr. with the disengagement of red or orange fumes. Its constituents are, 41.34 of hyponitrous acid, and 58.66 of anhydrous nitric acid; or ultimately, 30.68 nitrogen = 1 volume, and 69.32 oxygen = 2 volumes. In its other habitudes, it is quite analogous to hyponitrous acid.

A mixture of this double or compound acid with nitric acid, constitutes the orange-brown fuming nitrous acid of the British apothecaries.

The hyponitrous and nitrous are two acids remarkable for containing no water in their composition; being therefore *dry liquids*.

NOPAL is the Mexican name of the plant *cactus opuntia*, upon which the cochineal insect breeds.

NUTMEG (*Muscade*, Fr.; *Muskatennuss*, Germ.) is the fruit of the *myristica monchata*, a beautiful tree of the family of the *laurineæ* of Jussieu, which grows in the Moluccan islands. All the parts of this tree are very aromatic; but only those portions of the fruit called mace and nutmeg are sent into the market. The entire fruit is a species of *drupa*, of an ovoid form, of the size of a peach, and furrowed longitudinally. The nutmeg is the innermost kernel, or seed, contained in a thin shell, which is surrounded by the mace; and this again is enclosed in a tough fleshy skin, which opening at the tip, separates into two valves. The nutmeg tree yields three crops annually; one in April, which is the best; one in August; and one in December.

Good nutmegs should be dense, and feel heavy in the hand. When they have been perforated by worms, they feel light, and though the holes have been fraudulently stopped, the unsound ones may be easily detected by this criterion.

Nutmegs afford two oily products. 1. Butter of nutmeg, vulgarly called oil of mace, is obtained in the Moluccas, by expression, from the fresh nutmegs, to the amount of 50 per cent. of their weight. It is a reddish yellow butter-like substance, interspersed with light and dark streaks, and possesses the agreeable smell and taste of the nutmeg, from the presence of a volatile oil. It consists of two fats; one reddish and soft, soluble in cold alcohol; another white and solid, soluble in hot alcohol. 2. The volatile oil is solid, or a *stereoptene*, and has been styled *Myristicine*.

Imported in 1850, 315,126 lbs.; in 1851, 358,320 lbs.; exported, 1850, 151,526 lbs., in 1851, 107,495 lbs.; retained for home consumption, 1850, 168,403 lbs., in 1851, 194,132 lbs.; duty received, 1850, 19,042*l.*, 1851, 21,913*l.*

NUT OIL. See OILS, UNCTUOUS.

NUX VOMICA, a poisonous nut, remarkable for containing the *vegeto-alkal.* STRYCHNIA.

O.

OAK BARK. See TAN.

OATS. (*Avoine*, Fr.; *Hafer*, Germ.) The composition of oats is less known than that of the other *Cereal*ia. Vogel found that 100 parts of oats afforded 66 parts of flour or meal, and 34 parts of bran; but this proportion would depend upon the quality of the grain. The flour contains 2 parts of a greenish-yellow fat oil; 8.25 of bitterish sweet extractive; 2.5 of gum; 3.30 of a gray substance, more like coagulated albumen than gluten; 59 of starch; 24 of moisture (inclusive of the loss). Schrader found in the ashes of oats, silica, carbonate of lime, carbonate of magnesia, alumina, with oxides of manganese and iron.

OBSIDIAN, is a glassy-looking mineral, with a large conchoidal fracture, and of a blackish color, which froths much at the blow-pipe before it melts into a white enamel.

OCHRE, *yellow and brown* (*Ocre*, Fr.; *Ocker*, Germ.); is a native earthy mixture of silica and alumina, colored by oxide of iron, with occasionally a little calcareous matter and magnesia. Ochre occurs in beds some feet thick, which lie generally above the oolite, are covered by sandstone and quartzose sands more or less ferruginous, and are accompanied by gray plastic clays, of a yellowish or reddish color; all of them substances which contribute more or less to its formation. The ochry earths are prepared for use by grinding under edge millstones, and elutriation. The yellow ochres may be easily rendered red or reddish brown by calcination in a reverberatory oven, which oxidizes their iron to a higher degree.

Native red ochre is called red chalk and reddle in England. It is an intimate mixture of clay and red iron ochre; is massive; of an earthy fracture; is brownish-red, blood-red, stains and writes red. The oxyde of iron is sometimes so considerable, that the ochre may be reckoned an ore of that metal.

The ochre beds of England are in the iron sand, the lowest of the formations which intervene between the chalk and oolites. Beds of fuller's earth alternate with the iron sand. The following is a section of the ochre pits at Shotover Hill, near Oxford:

Beds of highly ferruginous grit, forming the summit of the hill	6 feet.
Gray sand	3 do.
Ferruginous concretions	1
Yellow sand	6
Cream colored loam	4
Ochre	0 6 inches.

Beneath this, there is a second bed of ochre, separated by a thin bed of clay.

Bole, or Armenian bole; called also Lemnian earth, and terra sigillata, because when refined it was stamped with a seal; is massive, with a conchoidal fracture, a feeble lustre, reddish-yellow or brown, a greasy feel; adheres to the tongue, spec. grav. 1.4 to 2.0. It occurs in the island Stalimene (the ancient Lesbos), and in several other places, especially at Sienna; whence the brown pigment called *terra di Siena*.

OILS (*Huiles*, Fr.; *Oele*, Germ.), are divisible into two great classes: the fat or fixed oils, *huiles grasses*, Fr.; *Fette oele*, Germ.; and the essential or volatile oils, *Huiles volatiles*, Fr.; *Flüchtige, aetherische oele*, Germ. The former are usually bland and mild to

to the taste; the latter hot and pungent. The term distilled, applied also to the last class, is not so correct, since some of them are obtained by expression, as the whole of the first class may be, and commonly are.

All the known fatty substances found in organic bodies, without reference to their vegetable or animal origin, are, according to their consistence, arranged under the chemical heads of oils, butters, and tallow. They all possess the same ultimate constituents, carbon, hydrogen, and generally oxygen, and in nearly the same proportions.

The following is a list of the Plants which yield the ordinary Unctuous Oils of commerce:

No.	Plants.		Oils.	Specific gravity.
1.	<i>Linum usitatissimum</i> et perenne	D.	Linseed Oil - - -	0.9347
2.	<i>Corylus avellana</i>	D.	Nut oil - - -	0.9260
3.	<i>Juglans regia</i>			
4.	<i>Papaver somniferum</i>	D.	Poppy oil - - -	0.9243
5.	<i>Cannabis sativa</i>	D.	Hemp oil - - -	0.9276
6.	<i>Sesamum orientale</i>	G.	Oil of sesamum - -	
7.	<i>Olea Europea</i>	G.	Olive oil - - -	0.9176
8.	<i>Amygdalus communis</i>	G.	Almond oil - - -	0.9180
9.	<i>Guilandina mohringa</i>	G.	Oil of behen or ben -

40.	<i>Æsculus hippocastanum</i>	G.	Horse-chestnut oil -	0.927
41.	<i>Pinus aties</i>	D.	Pinetop oil - - -	0.285

The fat oils are widely distributed through the organs of vegetable and animal nature. They are found in the seeds of many plants, associated with mucilage, especially in those of the bicotyledonous class, occasionally in the fleshy pulp surrounding some seeds, as the olive; also in the kernels of many fruits, as of the nut and almond tree, and finally in the roots, barks, and other parts of plants. In animal bodies, the oily matter occurs enclosed in thin membranous cells, between the skin and the flesh, between the muscular fibres, within the abdominal cavity in the omentum, upon the intestines, and round the kidneys, and in a bony receptacle of the skull of the sper-

maceti whale; sometimes in special organs, as of the beaver; in the gall bladder, &c. or mixed in a liquid state with other animal matters, as in the milk.

Braconnot, but particularly Raspail, have shown that animal fats consist of small microscopic, polygonal, and partly reniform particles, associated by means of their containing sacs. These may be separated from each other by tearing the recent fat asunder, rinsing it with water, and passing it through a sieve. The membranes being thus retained, the granular particles are observed to float in the water, and afterwards to separate, like the globules of starch, in a white pulverulent semi-crystalline form. The particles consist of a strong membranous skin, enclosing *stearine* and *elaine*, or solid and liquid fat, which may be extracted by trituration and pressure. These are lighter than water, but sink readily in spirit of wine. When boiled in strong alcohol, the oily principle dissolves, but the fatty membrane remains. These granules have different sizes and shapes in different animals; in the calf, the ox, the sheep, they are polygonal, and from $\frac{1}{10}$ to $\frac{1}{60}$ of an inch in diameter; in the hog they are kidney-shaped, and from $\frac{1}{10}$ to $\frac{1}{100}$ of an inch; in man, they are polygonal, and from $\frac{1}{10}$ to $\frac{1}{200}$ of an inch; in insects they are usually spherical, and not more than $\frac{1}{600}$ of an inch.

The fat oils are contained in that part of the seed which gives birth to the cotyledons, they are not found in the plumula and radicle. Of all the families of plants, the cruciform is the richest in oleiferous seeds; and next to that are the drupaceæ, amentaceæ, and solanaceæ. The seeds of the graminæ and leguminosæ contain rarely more than a trace of fat oil. One root alone, that of the *cyperus esculenta*, contains a fat oil. The quantity of oil furnished by seeds varies not only with the species, but in the same seed, with culture and climate. Nuts contain about half their weight of oil; the seeds of the *brassica oleracea* and *campestris*, one third; the variety called *colza* in France, two fifths; hempseed, one fourth; and linseed from one fourth to one fifth. Unverdorben states that a just or ten quarters of linseed yields 40 ahms=120 gallons English of oil; which is about 1 cwt. of oil per quarter.

The fat oils, when first expressed without much heat, taste merely unctuous on the tongue, and exhale the odor of their respective plants. They appear quite neutral by litmus paper. Their fluidity is very various, some being solid at ordinary temperatures, and others remaining fluid at the freezing point of water. Linseed oil indeed does not congeal till cooled from 4° to 18° below 0° F. The same kind of seed usually affords oils of different degrees of fusibility; so that in the progress of refrigeration one portion concretes before another. Chevreul, who was the first to observe this fact, considers all the oils to be composed of two species, one of which resembles *suet*, and was thence styled by him *stearine*; and another which is liquid at ordinary temperatures, and was called *elaine*, or *oleine*. By refrigeration and pressure between the folds of blotting paper, or in linen bags, the fluid part is separated, and the solid remains. By heating the paper in water, the liquid oil may be obtained separate. When alcohol is boiled with the natural oil, the greater part of the *stearine* remains undissolved.

Oleine may also be procured by digesting the oil with a quantity of caustic soda equal to one half of what is requisite to saponify the whole; the *stearine* is first transformed into soap, then a portion of the oleine undergoes the same change, but a great part of it remains in a pure state. This process succeeds only with recently expressed or very fresh oils. The properties of these two principles of the fat oils vary with the nature of the respective oils, so that the sole difference does not consist, as many suppose, in the different proportions of these two bodies, but also in peculiarities of the several *stearines* and *oleines*, which, as extracted from different seeds, solidify at very different temperatures.

In close vessels, oils may be preserved fresh for a very long time, but with contact of air they undergo progressive changes. Certain oils thicken and eventually dry into a transparent, yellowish, flexible substance; which forms a skin upon the surface of the oil, and retards its further alteration. Such oils are said to be *drying* or *siccative*, and are used on this account in the preparation of varnishes and painters' colors. Other oils do not grow dry, though they turn thick, become less combustible, and assume an offensive smell. They are then called *rancid*. In this state, they exhibit an acid reaction, and irritate the fauces when swallowed, in consequence of the presence of a peculiar acid, which may be removed in a great measure by boiling the oil along with water and a little common magnesia for a quarter of an hour, or till it has lost the property of reddening litmus. While oils undergo the above changes, they absorb a quantity of oxygen equal to several times their volume. Saussure found that a layer of nut oil, one quarter of an inch thick, enclosed along with oxygen gas over the surface of quicksilver in the shade, absorbed only three times its bulk of that gas in the course of eight months; but when exposed to the sun in August, it absorbed 60 volumes additional in the course of ten days. This absorption of oxygen diminished progressively, and stopped altogether at the end of three months, when it had amounted to 145 times the bulk of the oil. No water was generated, but 21.9 volumes of carbonic acid were disengaged, while the oil

was transformed in an anomalous manner into a gelatinous mass, which did not stain paper. To a like absorption we may ascribe the elevation of temperature which happens when wool or hemp, besmeared with olive or rapeseed oil, is left in a heap; circumstances under which it has frequently taken fire, and caused the destruction of both cloth-mills and dock-yards.

In illustration of these accidents, if paper, linen, tow, wool, cotton, mats, straw, wood shavings, moss, or soot, be imbued slightly with linseed or hempseed oil, and placed in contact with the sun and air, especially when wrapped or piled in a heap, they very soon become spontaneously hot, emit smoke, and finally burst into flames. If linseed oil and ground manganese be triturated together, the soft lump so formed will speedily become firm, and ere long take fire.

The fat oils are completely insoluble in water. When agitated with it, the mixture becomes turbid, but if it be allowed to settle the oil collects by itself upon the surface. This method of washing is often employed to purify oils. Oils are little soluble in alcohol, except at high temperatures. Castor oil is the only one which dissolves in cold alcohol. Ether, however, is an excellent solvent of oils, and is therefore employed to extract them from other bodies in analysis; after which it is withdrawn by distillation.

Fat oils may be exposed to a considerably high temperature, without undergoing much alteration; but when they are raised to nearly their boiling point, they begin to be decomposed. The vapors that then rise are not the oil itself, but certain products generated in it by the heat. These changes begin somewhere under 600° of Fahr., and require for their continuance temperatures always increasing. The products consist at first in aqueous vapor, then a very inflammable volatile oil, which causes boiling oil to take fire spontaneously; and next carbureted hydrogen gas, with carbonic acid gas. In a lamp, a small portion of oil is raised in the wick by capillarity, which being heated, boils and burns. See ROSIN-GAS.

Several fat oils, mixed with one or two per cent. of sulphuric acid, assume instantly a dark green or brown hue, and, when allowed to stand quietly, deposite a coloring matter after some time. It consists in a chemical combination of the sulphuric acid, with a body thus separated from the oil, which becomes in consequence more limpid, and burns with a brighter flame, especially after it is washed with steam, and clarified by repose or filtration. Any remaining moisture may be expelled by the heat of a water bath.

The oils combine with the salifiable bases, and give birth to the substance called *glycerine* (the sweet principle), and to the margaric, oleic, and stearic acids. The general product of their combination with potash or soda, is Soap, which see. Caustic ammonia changes the oils very difficultly and slowly into a soap; but it readily unites with them into a milky emulsion called volatile liniment, used as a rubefacient in medicine. Upon mixing water with this liquor, the oil separates in an unchanged state. By longer contact, ammonia acts upon oils like the other alkalis. Sea salt dissolves in small quantity in the oils, and so does verdigris. The latter solution is green. Oils dissolve also several of the vegetable alkalis, as morphia, cinchonia, quinia, strychnia, and delphinia.

Olive oil consists of 77.2 carbon, 13.4 hydrogen, and 9.4 oxygen, in 100 parts. Spermaceti oil, by my analysis, of 78.9 carbon, 10.97 hydrogen, and 10.13 oxygen.

Castor oil	do.	-	-	74.0	10.3	15.7	azote,
Stearine of olive oil		-	-	82.17	11.23	6.30	0.30 Saussure.
Oleine of	do.	-	-	76.03	11.54	12.07	0.35 do.
Linseed oil		-	-	76.01	11.35	12.64	do.
Nut oil		-	-	79.77	10.57	9.12	0.54 do.
Oil of almonds		-	-	77.40	11.48	10.83	0.29

De Saussure concludes that the less fusible fats contain more carbon and less oxygen, and that oils are more soluble in alcohol, the more oxygen they contain.

I shall now take a short view of the peculiarities of the principal expressed oils.

Oil of almonds, according to Gusserson, contains no stearine; at least he could obtain none by cooling it and squeezing it successively till it all congealed. Braconnot had, on the contrary, said, that it contains 24 per cent. of stearine. I believe that Gusserson is right, and that Braconnot had made fallacious experiments on an impure oil.

Oil of colza is obtained from the seeds of *brassica campestris*, to the amount of 39 per cent. of their weight. It forms an excellent lamp oil, and is much employed in France.

The *corylus avellana* furnishes in oil 60 per cent. of the weight of the nuts.

Hempseed oil resembles the preceding, but has a disagreeable smell, and a mawkish taste. It is used extensively for making both soft soap and varnishes.

Linseed oil is obtained in greatest purity by cold pressure; but by a steam heat of about 200° F. a very good oil may be procured in larger quantity. The proportion of

oil usually stated by authors is 22 per cent. of the weight of the seed; but Mr. Blandell informs me, that, by his plan of hydraulic pressure, he obtains from 26 to 27. In the Encyclopædia Metropolitana, under *Oil Press*, a quarter of seed (whose average weight is 400 lbs.) is said to yield 20 gallons of oil. Now as the gallon of linseed oil weighs 9·3 lbs., the total product will be 186 lbs., which amounts to more than 45 per cent.—an extravagant statement, about double the ordinary product in oil mills. Even supposing the gallons not to be imperial, but old English, we should have upwards of 38 per cent. of oil by weight, which is still an impossible quantity. Such are the errors introduced into respectable books, by adopting without practical knowledge, the puffing statements of a patentee. It dissolves in 5 parts of boiling alcohol, in 40 parts of cold alcohol, and in 1·6 parts of ether. When kept long cool in a cask partly open, it deposits masses of white stearine along with a brownish powder. That stearine is very difficult of saponification.

Mustard-seed oil. The white or yellow seed affords 36 per cent. of oil, and the black seed 18 per cent. The oil concretes when cooled a little below 32° F.

Nut oil is at first greenish colored, but becomes pale yellow by time. It congeals at the same low temperature as linseed oil, into a white mass, and has a more drying quality than it.

Oil of olives is sometimes of a greenish and at others of a pale yellow color. A few degrees above 32° F. it begins to deposit some white granules of stearine, especially if the oil have been originally expressed with heat. At 22° it deposits 28 per cent. of its weight in stearine, which is fusible again at 68°, and affords 72 per cent. of oleine. According to Kerwych, oleine of singular beauty may be obtained by mixing 2 parts of olive oil with 1 part of caustic soda ley, and macerating the mixture for 24 hours with frequent agitation. Weak alcohol must then be poured into it, to dissolve the stearine soap, whereby the oleine, which remains meanwhile unsaponified, is separated, and floats on the surface of the liquid. This being drawn off, a fresh quantity of spirits is to be poured in, till the separation of all the oleine be completed. It has a slightly yellowish tint, which may be removed by means of a little animal charcoal mixed with it in a warm place for 24 hours. By subsequent filtration, the oleine is obtained limpid and colorless, of such quality that it does not thicken with the greatest cold, nor does it affect either iron or copper instruments immersed in it.

There are three kinds of olive oil in the market. The best, called virgin salad oil, is obtained by a gentle pressure in the cold; the more common sort is procured by stronger pressure, aided with the heat of boiling water; and thirdly, an inferior kind, by boiling the olive residuum or *marc*, with water, whereby a good deal of mucilaginous oil rises and floats on the surface. The latter serves chiefly for making soaps. A still worse oil is got by allowing the mass of bruised olives to ferment before subjecting it to pressure.

Oil of olives is refined for the watchmakers by the following simple process. Into a bottle or phial containing it, a slip of sheet lead is immersed, and the bottle is placed at a window, where it may receive the rays of the sun. The oil by degrees gets covered with a curdy mass, which after some time settles to the bottom, while itself becomes limpid and colourless. As soon as the lead ceases to separate any more of that white substance, the oil is decanted off into another phial for use.

There are four different kinds of olive oil known in the districts where it is prepared: 1. the virgin oil; 2. the ordinary oil (*huile ordinaire*); 3. oil of the *infernal regions* (*huile d'enfer*); 4. oil prepared by fermentation.

1. *Virgin oil.* In the district Montpellier, they apply the term *virgin oil* to that which spontaneously separates from the paste of crushed olives. This oil is not met with in commerce, being all used by the inhabitants of the district, either as an emollient remedy, or for oiling the works of watches.

In the district of Aix, they give the name *virgin oil* to that which is first obtained from the olives ground to a paste in a mill, and submitted to a slight pressure 2 or 3 days after collecting the fruit. Thus, there is no virgin oil brought from Montpellier, but a good deal of it is brought from Aix.

2. *Ordinary oil.* In the district of Montpellier, this oil is prepared by pressing the olives, previously crushed and mixed with boiling water. At Aix the *ordinary oil* is made from the olives which have been used for obtaining the *virgin oil*. The paste, which has been previously pressed, is broken up, a certain quantity of boiling water is poured over it, and it is then again submitted to the press. By this second expression, in which more pressure is applied than in the previous one, an oil is obtained somewhat inferior in quality to the *virgin oil*. The oil is separated from the water in a few hours after the operation.

3. *Oil of the infernal regions* (*huile d'enfer*). The water which has been employed in the preceding operation, is, in some districts, conducted into large reservoirs, called the infernal regions, where it is left for many days. During this period, any oil that

might have remained mixed with the water separates, and collects on the surface. This oil being very inferior in quality, is only fit for burning in lamps, for which it answers very well. It is sometimes called *lamp oil*.

4. *Fermented oil (huile fermentée)*. This is obtained in the two above-named districts, by leaving the fresh olives in heaps for some time, and pouring boiling water over them before pressing the oil. But this method is very seldom put in practice, for the olives during this fermentation lose their peculiar flavour, become much heated, and acquire a musty taste, which is communicated to the oil.

The fruity flavour of the oil depends upon the quality of the olives from which it has been pressed, and not upon the method adopted in its preparation.

There are met with in commerce the virgin oil of Aix, rarely the oil obtained by fermentation, and never the oil of the infernal regions.

Palm oil melts at 117.5° F., and is said to consist of 31 parts of stearine and 69 of oleine in 100. It becomes readily rancid by exposure to air, and is whitened at the same time.

The oil extracted from the plucked tops of the *pinus abies*, in the Black Forest in Germany, is limpid, of a golden yellow color, and resembles in smell and taste the oil of turpentine. It answers well for the preparation of varnishes.

The oil of *plum-stones* is made chiefly in Wurtemberg, and is found to answer very well for lamps.

Poppy-seed oil has none of the narcotic properties of the poppy juice. It is soluble in ether in every proportion.

Rape-seed oil has a yellow color, and a peculiar smell. At 25° F. it becomes a yellow mass, consisting of 46 parts of stearine, which fuses at 50°, and 54 of oleine, in which the smell resides.

The oils of *belladonna seeds*, and *tobacco seeds*, are perfectly bland. The former is much used for lamps in Swabia and Wurtemberg. The oil-cakes of both are poisonous.

Oil of wine-stones is extracted to the amount of 10 or 11 per cent. from the seeds of the grape. Its color is at first pale yellow, but it darkens with age. It is used as an article of diet.

FAT OIL MANUFACTURE.

It is the practice of almost all the proprietors in the neighborhood of Aix, in Provence, to preserve the olives for 15 days in barns or cellars, till they have undergone a species of fermentation, in order to facilitate the extraction of their oil. If this practice were really prejudicial to the product, as some theorists have said, would not the high reputation and price of the oil of Aix have long ago suffered, and have induced them to change their system of working? In fact, all depends upon the degree of fermentation excited. They must not be allowed to mould in damp places, to lie in heaps, to soften so as to stick to each other, and discharge a reddish liquor, or to become so hot as to raise a thermometer plunged into the mass up to 96° F. In such a case they would afford an acrid nauseous oil, fit only for the woollen or soap manufactories. A slight fermentative action, however, is useful, towards separating the oil from the mucilage. The olives are then crushed under the stones of an edge-mill, and next put into a screw-press, being enclosed in bulrush-mat bags (*cabas*), laid over each other to the number of eighteen. The oil is run off from the channels of the ground-sill, into casks, or into stone cisterns called *pizes*, two thirds filled with water. The pressure applied to the *cabas* should be slowly graduated.

What comes over first, without heat, is the virgin oil already mentioned. The *cabas* being now removed from the press, their contents are shovelled out, mixed with some boiling water, again put in the bags, and pressed anew. The hot water helps to carry off the oil, which is received in other casks or *pizes*. The oil ere long accumulates at the surface, and is skimmed off with large flat ladles; a process which is called *lever l'huile*. When used fresh, this is a very good article, and quite fit for table use, but is apt to get rancid when kept. The subjacent water retains a good deal of oil, by the intervention of the mucilage; but by long repose in a large general cistern, called *Penfer*, it parts with it, and is then drawn off from the bottom by a plug-hole. The oil which remains after the water is run off, is of an inferior quality, and can be used only for factory purposes.

The marc being crushed in a mill, boiled with water, and expressed, yields a still coarser article.

All the oil must be *fined* by keeping in clean tuns, in an apartment heated to the 60th degree Fahr. at least, for twenty days; after which it is run off into strong casks, which are cooled in a cellar, and then sent into the market.

Oil of almonds is manufactured by agitating the kernels in bags, so as to separate their brown skins, grinding them in a mill, then enclosing them in bags, and squeezing

them strongly between a series of cast iron plates, in a hydraulic press; without heat at first, and then between heated plates. The first oil is the purest, and least apt to become rancid. It should be refined by filtering through porous paper. Next to olive oil, this species is the most easy to saponify. Bitter almonds, being cheaper than the sweet, are used in preference for obtaining this oil, and they afford an article equally bland, wholesome, and inodorous. But a strongly scented oil may be procured, according to M. Planché, by macerating the almonds in hot water, so as to blanch them then drying them in a stove, and afterwards subjecting them to pressure. The volatile oil of almonds is obtained by distilling the marc or bitter almond cake, along with water. See PRESS HYDRAULIC, and STEARINE.

Linseed, rapeseed, poppyseed, and other oleiferous seeds were formerly treated for the extraction of their oil, by pounding in hard wooden mortars with pestles shod with iron, set in motion by cams driven by a shaft turned with horse or water power, then the triturated seed was put into woollen bags which were wrapped up in hair-cloths, and squeezed between upright wedges in press-boxes by the impulsion of vertical rams driven also by a cam mechanism. In the best mills upon the old construction, the cakes obtained by this first wedge pressure were thrown upon the bed of an edge-mill, ground anew and subjected to a second pressure, aided by heat now, as in the first case. These mortars and press-boxes constitute what are called Dutch mills. They are still in very general use both in this country and on the Continent; and are by many persons supposed to be preferable to the hydraulic presses.

The roller-mill, for merely bruising the linseed, &c., previous to grinding it under edge-stones, and to heating and crushing it in a Dutch or a hydraulic oil-mill, is represented

in figs. 1012 and 1013. The iron shaft *a*, has a winch at each end, with a heavy fly-wheel upon the one of them, when the machine is to be worked by hand. Upon the opposite end is a pulley, with an endless cord which passes round a pulley on the end of the fluted roller *b*, and thereby drives it. This fluted roller *b*, lies across the hopper *c*, and by its agitation causes the seeds to descend equably through the hopper, between the crushing rollers *d*, *e*. Upon the shaft *a*, there is also a pinion which works into two toothed wheels on the shafts of the crushing cylinders *d* and *e*, thus communicating to these cylinders motion in opposite directions. *f*, *g* are two scraper-blades, which by means of the two weights *h*, *h*, hanging upon levers, are pressed against the surfaces of the cylinders, and remove any seed-cake from them. The bruised seeds fall through the slit *i* of the case, and are received into a chest which stands upon the board *k*.

Machines of this kind are now usually driven by power. Hydraulic presses have been of late years introduced into many seed-oil mills in this country; but it is still a matter of dispute whether they, or the old Dutch oil-mill, with bags of seed compressed between wedges, driven by cam-stamps, be the preferable; that is, afford the largest product of oil with the same expenditure of capital and power. For figures of hydraulic presses, see PRESS, and STEARINE.

This bruising of the seed is merely a preparation for its proper grinding under a pair of heavy edge stones, of granite, from 5 to 7 feet in diameter; because unbruised seed is apt to slide away before the vertical rolling wheel, and thus escape trituration. The edge-mill, for grinding seeds, is quite analogous to the gunpowder-mill represented in fig. 740, page 980. Some hoop the stones with an iron rim, but others prefer, and I think justly, the rough surface of granite, and dress it from time to time with hammers, as it becomes irregular. These stones make from 30 to 36 revolutions upon their

horizontal bed of masonry or iron in a minute. The centre of the bed, where it is perforated for the passage of the strong vertical shaft which turns the stones, is enclosed by a circular box of cast iron, firmly bolted to the bed-stone, and furnished with a cover. This box serves to prevent any seeds or powder getting into the step or socket, and obstructing the movement. The circumference of the mill-bed is formed of an upright rim of oak-plank, bound with iron. There is a rectangular notch left in the edge of the bed, and corresponding part of the rim, which is usually closed with a slide-plate, and is opened only at the end of the operation, to let the pasty seed-cake be turned out by the oblique arm of the bottom scraper. The two parallel stones, which are set near each other, and travel round their circular path upon the bed, grind the seeds not merely by their weight, of three tons each, but also by a rubbing motion, or attrition; because their periphery being not conical, but cylindrical, by its rolling upon a plane surface, must at every instant turn round with friction upon their resting points. Strong cast-iron boxes are bolted upon the centre of the stones, which by means of screw clamps seize firmly the horizontal iron shafts that traverse and drive them, by passing into a slit-groove the vertical turning shaft. This groove is lined with strong plates of steel, which wear rapidly by the friction, and need to be frequently renewed.

The seeds which have been burst between the rolls, or in the mortars of the Dutch mills, are to be spread as equably as possible by a shovel upon the circular path of the edge-stones, and in about half an hour the charge will be sufficiently ground into a paste. This should be put directly into the press, when fine cold-drawn oil is wanted. But in general the paste is heated before being subjected to the pressure. The pressed cake is again thrown under the edge-stones, and, after being ground the second time, should be exposed to a heat of 212° Fahr., in a proper pan, called a steam-kettle, before being subjected to the second and final pressure in the woollen bags and hair-cloths.

Fig. 1014 is a vertical section of the steam-kettle of Hallette, and fig. 1015 is a view of

the seed-stirrer. *a*, is the wall of masonry, upon which, and the iron pillars *b*, the pan is supported. It is enclosed in a jacket, for admitting steam into the intermediate space *d, d, d*, at its sides and bottom. *c*, is the middle of the pan in which the shaft of the stirrer is planted upright, resting by its lower end in the step *e*; *f*, is an opening, by which the contents of the pan may be emptied; *g*, is an orifice into which the mouth of the hair or worsted bag is inserted, in order to receive the heated seed, when it is turned out by the rotation of the stirrer and the withdrawal of the plug *f* from the discharge aperture; *h*, is the steam induction pipe; and *t*, the eduction pipe, which serves also to run off the condensed water.

The hydraulic oil-press is generally double; that is, it has two vertical rams placed parallel to each other, so that while one side is under pressure, the other side is being discharged. The bags of heated seed-paste or meal are put into cast-iron cases, which are piled over each other to the number of 6 or 8, upon the press sill, and subjected to a force of 300 or 400 tons, by pumps worked with a steam engine. The first pump has usually 2 or 2½ inches diameter for a ram of 10 inches, and the second pump one inch. Each side of the press, in a well-going establishment, should work 38 pounds of seed-flour every 5 minutes. Such a press will do 70 quarters of linseed in the days' work of one week, with the labor of one man at 20s. and three boys at 5s. each; and will require a 12-horse power to work it well, along with the rolls and the edge-stones.

I am indebted to my excellent friend Mr. E. Woosley, for the following most valuable notes, taken by him at sundry mills for pressing oil; and remarks upon the subject of seed-crushing in general.

"The chief point of difference depends upon the quality of seed employed. Heavy seed will yield most oil, and seed ripened under a hot sun, and where the flax is not gathered too green, is the best. The weight of linseed varies from 48 to 52 lbs. per imperial bushel; probably a very fair average is 49 lbs., or 392 lbs. per imperial quarter. I inspected one of the seed-crusher's books, and the average of 15 trials of a

quarter each of different seeds in the season averaged $14\frac{1}{2}$ galls. of $7\frac{1}{2}$ lbs. each; say, 109 lbs. of oil per quarter. This crusher, who uses only the hydraulic press, and one pressing, informed me that—

Archangel seed will yield from - - - - 15 to 16 galls. (of $7\frac{1}{2}$ lbs. each)
 Best Odessa - - - - 18 and even 19 galls.
 Good crushing-seed - - - - $15\frac{1}{2}$ do.
 Low seed, such as weighs 48 lbs. per bushel - $13\frac{1}{2}$ do.

"The average of the seed he has worked, which he represents to be of an inferior quality, for the sake of its cheapness, yields $14\frac{1}{2}$ galls. per quarter. I had some American seed which weighed $52\frac{1}{2}$ lbs. per imperial bushel, ground and pressed under my own observation, and it gave me 111 lbs. oil; that is to say, 418 lbs. of seed gave 111 lbs. oil= $26\frac{5}{10}$ per cent. A friend of mine, who is a London crusher, told me the oil varied according to the seed from 14 to 17 galls.; and when you consider the relative value of seeds, and remember that oil and cake from any kind of seed is of the same value, it will be apparent that the yield is very different; for example,

25th July, 1836, { E. India linseed worth 52s. per quarter.
 prices of seed. { Petersburg linseed 48 to 52 do.
 { Odessa - - - 52 - - -

The difference of 4s. must be paid for in the quantity of oil, which at 38s. 6d. per cwt. (the then price) requires about $11\frac{1}{2}$ lbs. more oil expressed to pay for the difference in the market value of the seed. Another London crusher informed me that East India linseed will produce 17 gallons, and he seemed to think that that was the extreme quantity that could be expressed from any seed. The average of last year's Russian seed would be about 14 galls.; Sicilian seed 16 galls.

Place.	Engine Power.	Hydraulic Presses.	Stampers.	Rollers.	Edge-stones.	Kettles	Work done,—reduced to an hour.	Number of pressings.
France	10 horse power	1 hydraulic, 200 tons.	5 light stampers.	1 pair rolls.	1 pr. edge-stones.	5 table kettles small size heated by steam.	1 English quarter per working hour.	2 pressings.
London	20 horse power	1 hydraulic, 800 tons.	13 light stampers.	1 pair rolls.	2 pr. edge-stones.	8 table kettles small size heated by fire.	2 English quarters per working hour.	2 ditto
London	12 horse power, but the engine is used also for other work.	none	9 light stampers.	2 pair rolls, used also for other purposes.	2 pr. edge-stones, used also for other purposes.	4 table kettles small size heated by fire.	$\frac{1}{2}$ English quarter per working hour.	2 ditto
Hull	18 horse engine, old construction.	none	3 very heavy stampers.	1 pair rolls.	1 pr. edge-stones.	3 double case large size steam kettles.	$1\frac{1}{2}$ English quarter per working hour.	1 ditto
Ditto	22 horse engine	none	6 very heavy stampers.	2 pair rolls.	2 pr. edge-stones.	6 double case large size steam kettles.	Not known.	1 ditto

"Rape-seed.—I have not turned my attention to the quantity of oil extracted from this seed; but a French crusher (M. Geremboret), on whom I think one may place considerable dependance, told me that

$3\frac{1}{2}$ lbs. of best Cambray rape-seed yielded - - - 1 lb. oil.
 $3\frac{3}{4}$ — common rape-seed - - - 1 lb. oil.
 $4\frac{1}{2}$ — poppy-seed - - - 1 lb. oil.

"Rape-seed weighs from 52 to 56 lbs. per imperial bushel."

The following are the heads of a reference of machinery for a seed oil-mill:—

1. Two pairs of cast-iron rollers, 19 inches long, and 10 inches in diameter, fixed in a cast-iron frame, with brasses, wheels, shafts, bolts, scrapers, hoppers, shoes, &c.
2. Two pairs of edge-stones, 7 feet diameter each, with two bottom stones, 6 feet diameter each, cast-iron upright shafts, sweepers, wheels, shafts, chairs, brasses, bolts, and scrapers, with driving spur-wheels, &c.
3. Five steam kettles, with wheels, shafts, and brasses, bolts, breeches, and steam pipes, an upright cast-iron shaft, with chairs and brasses at each end; and a large bevel wheel upon the bottom end of upright shaft, and another, smaller, upon fly-wheel shaft, for the first motions.

4. Five stamper presses, with press plates of cast-iron, cast-iron stamper shaft with 10 arms and 10 rollers, with bosses, brasses, bolts, driving bevel-wheels.

A well made oil-mill, consisting of the above specified parts, will manufacture 206 quarters of seed per week.

I have been assured by practical engineers, conversant in oil-mills, that a double hydraulic press, with 2 ten-inch rams, will do the work of no more than two of the stamper presses; that is to say, it will work 22 quarters in 24 hours; while three stamper presses will work 33 quarters in the same time, and produce one half more oil.

Oil, Cocoa-nut, imported in 1850, 98,040 cwt., in 1851, 55,994 cwt.

Oil, Olive, imported in 1850, 20,784 tons, in 1851, 11,488 tons.

Oil, Train, Blubber, and Spermaceti, imported in 1850, 21,859 tons, in 1851, 22,219 tons. For Seal Oil, see SEAL FISHERY.

OILS, VOLATILE OR ESSENTIAL; Manufacture of. The volatile oils occur in every part of odoriferous plants, whose aroma they diffuse by their exhalation; but in different organs of different species. Certain plants, such as thyme and the scented *labiales*, in general contain volatile oil in all their parts; but others contain it only in the blossoms, the seeds, the leaves, the root, or the bark. It sometimes happens that different parts of the same plant contain different oils; the orange, for example, furnishes three different oils, one of which resides in the flowers, another in the leaves, and a third in the skin or epidermis of the fruit. The quantity of oil varies not only with the species, but also in the same plant, with the soil, and especially the climate; thus in hot countries it is generated most profusely. In several plants, the volatile oil is contained in peculiar orders of vessels, which confine it so closely that it does not escape in the drying, nor is dissipated by keeping the plants for many years. In other species, and particularly in flowers, it is formed continually upon their surface, and flies off at the moment of its formation.

Volatile oils are usually obtained by distillation. For this purpose the plant is introduced into a still, water is poured upon it, and heat being applied, the oil is volatilized by the aid of the watery vapor, at the temperature of 212° , though when alone it would probably not distil over unless the heat were 100° more. This curious fact was first explained in my *New Researches upon Heat*, published in the Philosophical Transactions for 1818. Most of the essential oils employed in medicine and perfumery are extracted by distillation from dried plants; only a few, such as those of the rose and orange flower, are obtained from fresh or succulent salted plants. When the mingled vapors of the oil and water are condensed into the liquid state, by the refrigerator of the still, the oil separates, and either floats on the surface or sinks to the bottom of the water. Some oils of a less volatile nature require a higher heat than 212° to raise them in vapor, and must be dislodged by adding common salt to the water, whereby the heat being augmented by 15° , they readily come over. If in such distillations too much water be added, no oil will be obtained, because it is partially soluble in water; and thus merely an aromatic water is produced. If on the other hand too little water be used, the plant may happen to adhere to the bottom of the still, get partially charred, and thus impart an empyreumatic odor to the product. But as the quality of water distilled depends less upon the quantity employed, than upon that of the surface exposed to the heat, it is obvious that by giving a suitable form to the still, we may get rid of every inconvenience. Hence the narrower and taller the alembic is, within certain limits, the greater will be the proportion of oil relative to that of the aromatic water, from like proportions of aqueous and vegetable matter employed. Some place the plants in baskets, and suspend these immediately over the bottom of the still under the water, or above its surface in the steam. But the best mode in my opinion is to stuff an upright cylinder full of the plants, and to drive down through them, steam of any desired force; its tension and temperature being further regulated by the size of the outlet orifice leading to the condenser. The cylinder should be made of strong copper tinned inside, and incased in the worst conducting species of wood, such as soft deal or sycamore.

The distillation is to be continued as long as the water comes over of a milky appearance. Certain plants yield so little oil by the ordinary processes, notwithstanding every care, that nothing but a distilled water is obtained. In this case, the same water must be poured upon a fresh quantity of the plants in the still; which being drawn over, is again to be poured upon fresh plants; and thus repeatedly, till a certain dose of oil be separated. This being taken off, the saturated water is reserved for a like distillation.

The refrigeratory vessel is usually a worm or serpentine plunged in a tub of water, whose temperature should be generally cold; but for distilling the oils of anise-seed, fennel, &c., which become concrete at low temperatures, the water should not be cooler than 45° F.

The liquid product is commonly made to run at the worm end, into a vessel called an Italian or Florentine receiver, which is a conical matrass, standing on its base, with a pipe rising out of the side close to the bottom, and recurved a little above the middle

of the flask like the spout of a coffee-pot. The water and the oil collected in this vessel soon separate from each other, according to their respective specific gravities; the one floating above the other. If the water be the denser, it occupies the under portion of the vessel, and continually overflows by the spout in communication with the bottom, while the lighter oil is left. When the oil is the heavier of the two, the receiver should be a large inverted cone, with a stopcock at its apex to run off the oil from the water when the separation has been completed by repose. A funnel, having a glass stopcock attached to its narrow stem, is the most convenient apparatus for freeing the oil finally from any adhering particles of water. A cotton wick dipped in the oil may also serve the same purpose by its capillary action. The less the oil is transvased the better, as a portion of it is lost at every transfer. It may occasionally be useful to cool the distilled water by surrounding it with ice, because it thus parts with more of the oil with which it is impregnated.

There are a few essential oils which may be obtained by expression, from the substances which contain them; such as the oils of lemons and bergamot, found in the pellicle of the ripe fruits of the *citrus aurantium* and *medica*; or the orange and the citron. The oil comes out in this case with the juice of the peel, and collects upon its surface.

For collecting the oils of odoriferous flowers which have no peculiar organs for imprisoning them, and therefore speedily let them exhale, such as violets, jasmine, tuberose, and hyacinth, another process must be resorted to. Alternate layers are formed of the fresh flowers, and thin cotton fleece or woollen cloth-wadding, previously soaked in a pure and inodorous fat oil. Whenever the flowers have given out all their volatile oil to the fixed oil upon the fibrous matter, they are replaced by fresh flowers in succession, till the fat oil has become saturated with the odorous particles. The cotton or wool wadding being next submitted to distillation along with water, gives up the volatile oil. Perfumers alone use these oils; they employ them either mixed as above, or dissolve them out by means of alcohol. In order to extract the oils of certain flowers, as for instance of white lilies, infusion in a fat oil is sufficient.

Essential oils differ much from each other in their physical properties. Most of them are yellow, others are colorless, red, or brown; some again are green, and a few are blue. They have a powerful smell, more or less agreeable, which immediately after their distillation is occasionally a little rank, but becomes less so by keeping. The odor is seldom as pleasant as that of the recent plant. Their taste is acrid, irritating, and heating, or merely aromatic when they are largely diluted with water or other substances. They are not greasy to the touch, like the fat oils, but on the contrary make the skin feel rough. They are almost all lighter than water, only a very few falling to the bottom of this liquid; their specific gravity lies between 0.847 and 1.096; the first number denoting the density of oil of citron, and the second that of oil of saffras. Although styled volatile oils, the tension of their vapor, as well as its specific heat, is much less than that of water. The boiling point differs in different kinds, but it is usually about 316° or 320° Fahr. Their vapors sometimes render reddened litmus paper blue, although they contain no ammonia. When distilled by themselves, the volatile oils are partially decomposed; and the gaseous products of the portion decomposed always carry off a little of the oil. When they are mixed with clay or sand, and exposed to a distilling heat, they are in a great measure decomposed; or when they are passed in vapor through a red-hot tube, combustible gases are obtained, and a brilliant porous charcoal is deposited in the tube. On the other hand, they distil readily with water, because the aqueous vapor formed at the surface of the boiling fluid carries along with it the vapor of the oil produced in virtue of the tension which it possesses at the 212th degree Fahr. In the open air, the volatile oils burn with a shining flame, which deposits a great deal of soot. The congealing point of the essential oils varies greatly; some do not solidify till cooled below 32°, others at this point, and some are concrete at the ordinary temperature of the atmosphere. They comport themselves in this respect like the fat oils; and they probably consist, like them, of two different oils, a solid and a fluid; to which the names *stearoptène* and *oleoptène*, or stearessence and oleiessence, may be given. These may be separated from each other by compressing the cooled concrete oil between the folds of porous paper; the stearessence remains as a solid upon the paper; the oleiessence penetrates the paper, and may be recovered by distilling it along with water.

When exposed to the air, the volatile oils change their color, become darker, and gradually absorb oxygen. This absorption commences whenever they are extracted from the plant containing them; it is at first considerable, and diminishes in rapidity as it goes on. Light contributes powerfully to this action, during which the oil disengages a little carbonic acid, but much less than the oxygen absorbed; no water is formed. The oil turns gradually thicker, loses its smell, and is transformed into a resin, which becomes eventually hard. De Saussure found that oil of lavender, recently distilled, had absorbed in four winter months, and at a temperature below 54° F., 52 times its

volume of oxygen, and had disengaged twice its volume of carbonic acid gases; nor was it yet completely saturated with oxygen. The steareness of anise-seed oil absorbed at its liquefying temperature, in the space of two years, 156 times its volume of oxygen gas, and disengaged 26 times its volume of carbonic acid gas. An oil which has begun to experience such an oxydization is composed of a resin dissolved in the unaltered oil; and the oil may be separated by distilling the solution along with water. To preserve oils in an unchanged state, they must be put in vials, filled to the top, closed with ground glass stopples, and placed in the dark.

Volatile oils are little soluble in water, yet enough so as to impart to it by agitation their characteristic smell and taste. The water which distils with any oil is in general a saturated solution of it, and as such is used in medicine under the name of distilled water. It often contains other volatile substances contained in the plants, and hence is apt to putrefy and acquire a nauseous smell when kept in perfectly corked bottles; but in vessels partially open, these parts exhale, and the water remains sweet. The waters, however, which are made by agitating volatile oil with simple distilled water, are not apt to spoil by keeping in well-corked bottles.

The volatile oils are soluble in alcohol, and the more so the stronger the spirit is. Some volatile oils, devoid of oxygen, such as the oils of turpentine and citron, are very sparingly soluble in dilute alcohol; while the oils of lavender, pepper, &c. are considerably so. De Saussure has inferred from his experiments that the volatile oils are the more soluble in alcohol, the more oxygen they contain. Such combinations form the odoriferous spirits which the perfumers incorrectly call waters, as *lavender water*, *eau de Cologne*, *eau de jasmin*, &c. They become turbid by admixture of water, which seizes the alcohol, and separates the volatile oils. Ether also dissolves all the essential oils.

These oils combine with several vegetable acids, such as the acetic, the oxalic, the succinic, the fat acids (stearic, margaric, oleic), the camphoric, and suberic.

With the exception of the oil of cloves, the volatile oils do not combine with the salifiable bases. They have been partially combined with caustic alkali, as in the case of Starkey's soap. This is prepared by triturating recently fused caustic soda in a mortar, with a little oil of turpentine, added drop by drop, till the mixture has acquired the consistence of soap. The compound is to be dissolved in spirits of wine, filtered, and distilled. What remains after the spirit is drawn off, consists of soda combined with a resin formed in the oil during the act of trituration.

The volatile oils in general absorb six or eight times their bulk of ammoniacal gas; but that of lavender absorbs 47 times.

The essential oils dissolve all the fat oils, the resins, and the animal fats.

In commerce these oils are often adulterated with fat oils, resins, or balsam of capivi dissolved in volatile oil. This fraud may be detected by putting a drop of the oil on paper, and exposing it to heat. A pure essential oil evaporates without leaving any residuum, whilst an oil mixed with any of the above substances leaves a translucent stain upon the paper. If fat oil be present, it will remain undissolved, on mixing the adulterated essential oil with thrice its volume of spirit of wine of specific gravity 0.840. Resinous matter mixed with volatile oil is easily detected, being left in the alembic after distillation. Oil diluted with spirit of wine, forms a milky emulsion on the addition of water; the alcoholic part is absorbed by the water, and the oil afterwards found on the surface, in a graduated glass tube, will show by its quantity the amount of the adulteration.

But it is more difficult to detect the presence of a cheap essential oil in a dear one, which it resembles. Here the taste and smell are our principal guides. A few drops of the suspected oil are to be poured upon a bit of cloth, which is to be shaken in the air, and smelled to from time to time. In this way we may succeed in distinguishing the odor of the oil which exhales at the beginning, and that which exhales at the end; a method which serves perfectly to detect oil of turpentine in the finer essential oils. Moreover, when the debased oil is mixed with spirits of wine at sp. gr. 0.840, the oil of turpentine remains in a great measure undissolved. If an oil heavier than water, and an oil lighter than water, be mixed, they may be separated by agitation for some time with that liquid, and then leaving the mixture at rest. Essential oils may also be distinguished by a careful examination of their respective densities.

Oil of bitter almonds is prepared by exposing the bitter almond cake, from which the bland oil has been expressed, in a sieve to the vapor of water rising within the still. The steam, as it passes up through the bruised almond *parenchyma*, carries off its volatile oil, and condenses along with it in the worm. The oil which first comes over, and which falls to the bottom of the water, has so pungent and penetrating a smell, that it is more like cyanogen gas than hydrocyanic or prussic acid. This oil has a golden yellow color, it is heavier than water; when much diluted, it has an agreeable smell, and a bitter burning taste. When exposed to the air, it absorbs oxygen, and lets fall a heap of crystals of benzoic acid. This oil consists of a mixture of two oils; one of which is volatile, contains hydrocyanic acid, and is poisonous; the other is less volatile, is not poisonous,

absorbs oxygen, and becomes benzoic acid. If we dissolve 100 parts of the oil of bitter almonds in spirit of wine, mix with the solution an alcoholic solution of potash, and then precipitate the oil with water, we shall obtain a quantity of cyanide of potash, capable of producing $22\frac{1}{2}$ parts of prussian blue. Oil of bitter almonds combines with the alkalis. Perfumers employ a great quantity of this oil in scenting their soaps. One manufacturer in Paris is said to prepare annually 3 cwt. of this oil. A similar poisonous oil is obtained by distilling the following substances with water: the leaves of the peach (*amygdalus persica*), the leaves of the bay-laurel (*prunus lauro-cerasus*), the bark of the plum tree (*prunus padus*), and the bruised kernels of cherry and plumstones. All these oils contain hydrocyanic acid, which renders them poisonous, and they also generate benzoic acid, by absorbing oxygen on exposure to air.

Oil of bitter almonds, in the crude state, consists of *hydruret of benzoyle*, *hydrocyanic acid*, *benzoic acid*, and *benzoin*. The two first constituents are essential ones; the others being accidental, and the result of spontaneous reactions.

The hydruret of benzoyl when pure is colourless, transparent, of spec. grav. 1.043; and though it possesses the almond flavour, is not poisonous; it ought to form 85 to 90 per cent. in volume of the crude oil. When oil of vitriol is mixed with that essential oil, it merely gives it a dark reddish brown colour, but does not decompose it. If the said hydruret, however, be exposed to the air, it becomes oxidized, and by the substitution of one atom of oxygen for one of hydrogen, it is transformed into benzoic acid; a compound often present in oil of bitter almonds. This acid is not coloured by oil of vitriol. Benzoin when present, however, forms a violet coloured compound with sulphuric acid.

Hydrocyanic acid sometimes is present to the extent of 8 or 10 per cent. in crude oil of bitter almonds, rendering the mixture poisonous.

To detect alcohol in oil of bitter almonds, nitric acid of specific gravity 1.42 may be employed, as I did in testing for alcohol in wood spirit.* If the oil be free from alcohol, no immediate action occurs, but in the course of 3 or 4 days crystals of benzoic acid begin to appear, and eventually occupy the whole bulk, giving a bright emerald green colour: this quiet reaction is very characteristic. But if alcohol to the amount of 8 or 10 per cent. be present, a violent effervescence ensues in a few minutes after pouring in the nitric acid, with the disengagement of nitrous fumes. By using nitric acid of 1.5 a very small proportion of alcohol may be recognized.

Essential oil of bitter almonds, free from adulteration, should have a specific gravity at most of 1.52.

When the crude oil of bitter almonds, and a mixture of milk of lime and protochloride of iron are all agitated together, and subjected to distillation at a gentle heat, the product is an oil of bitter almonds free from hydrocyanic acid.

Oil essential of bitter almonds. To determine whether the pure oil of bitter almonds, (hydruret of benzoyle) be poisonous or not, Mr. G. D. Grindley, of the Pharmaceutical school, made the following researches. He at first adopted the usual plan for removing the hydrocyanic acid, by distilling the commercial oil of almonds with a mixture of protochloride of iron and lime; the product was still contaminated with the acid, and several repetitions, conducted with every precaution, were attended with no better success. He then adopted, by the suggestion of Professor Redwood, the following method, which proved most satisfactory. The oil was mixed with an equal quantity of water, and digested in a water bath with red oxide of mercury, and small quantities of lime and protochloride of iron; time having been allowed for the decomposition of the acid the whole was introduced into a copper retort on account of the jumpings during distillation. The product consisted of pure hydruret of benzoyle, while bichloride of mercury, benzoate of lime, chloride of calcium, and oxide of iron, remained in the retort, with benzoine and an excess of the ingredients employed. The process is founded upon the strong affinity which exists between mercury and cyanogen, so that when binocide of mercury and hydrocyanic acid are digested together, they are decomposed, by cyanide of mercury and water being formed. The protochloride of iron, which with the lime yields protoxide, is introduced to prevent the formation of benzoic acid from the oxidation of the oil. For the same reason care should be taken to conduct the process with as little access of air as possible. The oil thus procured was pure and colourless. No trace of nitrogen could be detected by Lassaigne's test, which he found to be exceedingly delicate, affording indications of the presence of that body in extremely minute quantities of morphia, narcotine, &c. This test consists, in adding to a very small quantity of the substance to be tested, in a small German glass tube, a fragment of potassium about the size of a millet seed, and heating the tube over the flame of a spirit lamp, till the organic substance is entirely carbonized. The carbonaceous residue is treated with cold water, and to the clear decanted liquor a drop of a solution containing the mixed two oxides of iron is added. A dirty green precipitate is immediately formed, which if nitro-

* See the pamphlet, *Revenue in Jeopardy*.

gen be present is changed into a bright blue, on the addition of a drop of hydrochloric acid. This pure oil was administered to rabbits without injurious effect on their health or spirits. Bitter almond oil should be always purified by this valuable process of Messrs. Redwood and Grindley.

Oil of anise-seed is extracted by distillation from the seeds of the *pimpinella anisum*. It is either colorless, or has merely a faint yellow color, with the smell and taste of the seed. It concretes in lamellar crystals at the temperature of 50°, and does not melt again till heated to 64° nearly. Its specific gravity at 61° is 0.9958, and at 77°, 0.9857. It is soluble in all proportions in alcohol of 0.806; but only to the extent of 42 per cent. in alcohol of 0.84. When it becomes resinous by long exposure to the air, it loses its congealing property. It consists of two oils; a solid steareness, and a liquid oleiessence, which may be separated by compression of the cold concrete oil.

Oil of bergamot is extracted by pressure from the rind of the ripe fruit of the *citrus bergamium* and *aurantium*. It is a limpid, yellowish fluid, having a smell resembling that of oranges. Its specific gravity varies from 0.888 to 0.885. It becomes concrete when cooled a little below 32°.

Oil of cajeput is prepared in the Moluccas, by distilling the dry leaves of the *melaleuca leucadendron*. Cajeput is a native word, signifying merely a white tree. This oil is green; it has a burning taste, a strong smell of camphor, turpentine, and savine. It is very fluid, and at 48° has a specific gravity of 0.948. The color seems to be derived from the copper vessels in which it is imported, so that it is removed by distillation with water, which also separates the oil into two sorts; the first which comes over having a density of 0.897, the last of 0.920. This has a green color.

The oil of *caraway* is extracted from the seeds of the *carum carui*. It has a pale yellow color, and the smell and taste of the plant. Its specific gravity is 0.960. The seeds of the *cuminum cyminum* (cumin) afford an oil similar to the preceding, but not so agreeable. Its specific gravity is 0.975.

The oil of *cassia*, from the *laurus cassia*, is yellow passing into brown, has a specific gravity of 1.071, and affords a crystalline steareness by keeping in a somewhat open vessel.

The oil of *chamomile* is extracted by distillation from the flowers of the *matricaria chamomilla*. It has a deep blue color, is almost opaque, and thick; and possesses the peculiar smell of the plant. In the atmosphere it becomes brown and unctuous. If an ounce of oil of lemons be added to 3 pounds of this oil, they make it separate more readily from the adhering water.

Other blue oils, having much analogy with oil of chamomile, are obtained by distilling the following plants: Roman chamomile (*anthesis nobilis*), the flowers of *arnica montana*, and those of milfoil (*achillea millefolia*). The last has a spec. grav. of 0.852.

Oil of cinnamon is extracted by distillation from the bark of the *laurus cinnamomum*. It is produced chiefly in Ceylon, from the pieces of bark unfit for exportation. It is distilled over with difficulty, and the process is promoted by the addition of salt water, and the use of a low still. It has at first a pale yellow color, but it becomes brown with age. It possesses in a high degree both the sweet burning taste, and the agreeable smell of cinnamon. It is heavier than water; its specific gravity being 1.035. It concretes below 32° F., and does not fuse again till heated to 41°. It is very sparingly soluble in water, and when agitated with it readily separates by repose. It dissolves abundantly in alcohol, and combines with ammonia into a viscid mass, not decomposed on exposure to air.

When oil of cinnamon is kept for a long time, it deposits a steareness in large regular colorless or yellow crystals, which may be pulverized, and which melt at a very gentle heat into a colorless liquid, which crystallizes on cooling. It has an odor intermediate between that of cinnamon and vanilla; and a taste at first greasy, but afterwards burning and aromatic. It crackles between the teeth. It requires a high temperature for distillation, and becomes then brown and empyreumatic. It is very soluble in alcohol.

The oil of *cloves* is extracted from the dried flower buds of the *caryophyllus aromaticus*. It is colorless, or yellowish, has a strong smell of the cloves, and a burning taste. Its specific gravity is 1.061. It is one of the least volatile oils, and the most difficult to distil. At the end of a certain time it deposits a crystalline concrete oil. A similar steareness is obtained by boiling the bruised cloves in alcohol, and letting the solution cool. The crystals thus formed are brilliant, white, grouped in globules, without taste and smell. Oil of cloves has remarkable chemical properties. It dissolves in alcohol, ether, and acetic acid. It does not solidify at a temperature of 4° under 0° F., even when exposed to that cold for several hours. It absorbs chlorine gas, becomes green, then brown, and turns resinous. Nitric acid makes it red, and if heated upon it, converts it into oxalic acid. If mixed by slow degrees with one third of its weight of sulphuric acid, an acid liquor is formed, at whose bottom a resin of a fine purple color is

found. After being washed, this resin becomes hard and brittle. Alcohol dissolves it, and takes a red color; and water precipitates it of a blood red hue. It dissolves also in ether. When we agitate a mixture of strong caustic soda ley and oil of cloves in equal parts, the mass thickens very soon, and forms delicate lamellar crystals. If we then pour water upon it, and distil, there passes along with the water, a small quantity of an oil which differs from oil of cloves both in taste and chemical properties. During the cooling, the liquor left in the retort lets fall a quantity of crystalline needles, which being separated by expression from the alkaline liquid, are almost inodorous, but possess an alkaline taste, joined to the burning taste of the oil. These crystals require for solution from 10 to 12 parts of cold water. Potash ley produces similar effects. Ammoniacal gas transmitted through the oil is absorbed and makes it thick. The concrete combination thus formed remains solid as long as the vial containing it is corked, but when opened, the compound becomes liquid; and these phenomena may be reproduced as many times as we please. Such combinations are decomposed by acids, and the oil set at liberty has the same taste and smell as at first, but it has a deep red color. The alkalis enable us to detect the presence of other oils, as that of turpentine or sassafras, in that of cloves, because they fix the latter, while the former may be volatilized with water by distilling the mixture. The oil of cloves found in commerce is not pure, but contains a mixture of the tincture of pinks or clove-gillyflowers, whose acrid resin is thereby introduced. It is sometimes sophisticated with other oils.

The oil of elder is extracted by distillation from the flowers of the *sambucus nigra*. It has the consistence of butter. The watery solution is used in medicine.

Oil of fennel is extracted by distillation from the seeds of the *anethum feniculum*. It is either colorless or of a yellow tint, has the smell of the plant, and a specific gravity of 0.997. When treated with nitric acid, it affords benzoin. It congeals at the temperature of 14° F., and then yields by pressure a solid and a liquid oil; the former appearing in crystalline plates. It is used in this country for scenting soap.

Oils of fermented liquors. The substances usually fermented contain a small quantity of essential oils, which become volatile along with the alcoholic vapors in distillation, and progressively increase as the spirits become weaker towards the end of the process. The vapors then condense into a milky liquor. These oils adhere strongly to the alcohol, and give it a peculiar acrid taste. They differ according to the vinous wash from which they are obtained, and combine with greater or less facility with caustic alkalis.

1. *Oil of grain spirits.* At the ordinary temperature it is partially a white solid; when cooled lower it assumes the aspect of suet, and therefore consists chiefly of stear-essence. Its taste and smell are most offensive; it swims upon the surface of water, and even of spirit containing 30 per cent. of alcohol. It sometimes derives a green color from the copper worm of the still. When heated it fuses and turns yellow. When it has become resinous by the agency of the atmosphere, it gives a greasy stain to paper. It dissolves in 6 parts of anhydrous alcohol, and in two of ether; and is said to crystallize when the spirit solution has been saturated with it hot, and is allowed to cool. By exposure to a freezing mixture, the whiskey which contains it lets it fall. Caustic potash dissolves it very slowly, and forms a soap soluble in 60 parts of water. It is absorbed by wood charcoal, and still better by bone black; whereby it may be completely abstracted from bad whiskey. According to Buchner, another oil may also be obtained from the residuum of the second distillation of whiskey, if saturated with sea salt, and again distilled. Thus we obtain a pale yellow fluid oil, which does not concrete with cold, possessed of a disagreeable smell and acrid taste. Its specific gravity is 0.835. It is soluble in alcohol and ether.

2. *The oil from potato spirits* has properties quite different from the preceding. It is obtained in considerable quantity by continuing the distillation after most of the alcohol has come over, and it appears in the form of a yellowish oil, mixed with water and spirits. After being agitated first with water, then with a strong solution of muriate of lime, and distilled afresh, it possesses the following properties; it is colorless, limpid, has a peculiar smell, and a bitter hot taste of considerable permanence. It leaves no greasy stain upon paper, remains liquid at 0° F., but cooled below that point it crystallizes like oil of anise-seed. When pure it boils at 257° F.; but at a lower degree, if it contains alcohol. Its specific gravity is 0.821, or 0.823 when it contains a little water. It burns with a clear flame without smoke, but it easily goes out, if not burned with a wick. It dissolves in small quantity in water, to which it imparts its taste and the properties of forming a lather by agitation. It dissolves in all proportions in alcohol. Chlorine renders it green. Concentrated sulphuric acid converts it into a crimson solution, from which it is precipitated yellow by water. It dissolves in all proportions in acetic acid. Concentrated caustic leys dissolve it, but give it up to water. It does not appear to be poisonous, like the oil of corn spirits; because, when given by spoonfuls to dogs, it produced no other effect but vomiting.

3. The oil of brandy or grape spirits is obtained during the distillation of the fermented residuum of expressed grapes; being produced immediately after the spirituous liquor has passed over. It is very fluid, limpid, of a penetrating odor, and an acrid disagreeable taste. It grows soon yellow in the air. When this oil is distilled, the first portions of it pass unchanged, but afterwards it is decomposed and becomes empyreumatic. It dissolves in 1000 parts of water, and communicates to it its peculiar taste and smell. One drop of it is capable of giving a disagreeable flavor to ten old English gallons of spirits. It combines with the caustic alkalis, and dissolves sulphur.

Oil of juniper is obtained by distilling juniper berries along with water. These should be bruised, because their oil is contained in small sacs or reservoirs, which must be laid open before the oil can escape. It is limpid and colorless, or sometimes of a faint greenish yellow color. Its specific gravity is 0.911. It has the smell and taste of the juniper. Water, or even alcohol, dissolves very little of it. Gin contains a very minute quantity of this oil. Like oil of turpentine, it imparts to the urine of persons who swallow it, the smell of violets. Oil of juniper is frequently sophisticated with oil of turpentine introduced into the still with the berries; a fraud easily detected by the diminished density of the mixture.

The oil of lavender is extracted from the flowering spike of the *lavandula spica*. It is yellow, very fluid, has a strong odor of the lavender, and a burning taste. The specific gravity of the oil found in commerce is 0.898 at the temperature of 72° F., and of 0.877 when it has been rectified. It is soluble in all proportions in alcohol of 0.830, but alcohol of 0.887 dissolves only 42 per cent. of its weight. The fresh oil detonates slightly when mixed with iodine, with the production of a yellow cloud. There occurs in commerce a kind of oil of lavender known under the name of oil of *aspic* or oil of *spike*, extracted by distillation from a wild variety of the *lavandula spica*, which has large leaves, and is therefore called *latifolia*. This oil is manufactured in the south of Europe. Its odor is less characteristic than that of the lavender, resembling somewhat that of oil of turpentine, with which it is indeed often adulterated. It is also so cheap as to be sometimes used instead of the latter oil. Oil of lavender deposits, when partially exposed to the air, a concrete oil, which resembles camphor, to the amount of one fourth of its weight.

Oil of lemons is extracted by pressure from the yellow peel of the fruit of the lemon, or *citrus medica*. In this state it is a yellowish fluid, having a specific gravity of 0.8517; but when distilled along with water till three fifths of the oil have come over, it is obtained in a colorless state, and of a specific gravity of 0.847 at 72° F. This oil does not become concrete till cooled to 4° below 0° F.

The oil of lemons has a very agreeable smell of the fruit, which is injured by distillation. It is soluble in all proportions in anhydrous alcohol, but only 14 parts dissolve in 100 of spirits of wine of specific gravity 0.837. This oil, especially when distilled, forms with muriatic acid similar camphorated compounds with oil of turpentine, absorbing no less than 280 volumes of the acid gas.

Oil of lemons kept long, in ill-corked bottles, generates a quantity of stearacene, which when dissolved in alcohol, precipitated by water, and evaporated, affords brilliant, colorless, transparent needles. Some acetic acid is also generated in the old oil. According to Brandes, the specific gravity of oil of lemons is 0.8786.

The oil of mace lets fall, after a certain time, a concrete oil under the form of a crystalline crust, called by John myristicine.

The oil of nutmegs is extracted chiefly from mace, which is the inner epidermis of these nuts. It is colorless, or yellowish, a little viscid with a strong aromatic odor of nutmegs, an acrid taste, and a specific gravity of 0.948. It consists of two oils, which may be easily separated from each other by agitation with water; for one of them, which is more volatile and aromatic, comes to the surface, while the other, which is denser, white, and of a buttery consistence, falls to the bottom. The latter liquefies by the heat of the hand.

The oil of orange flowers, called *neroli*, is extracted from the fresh flowers of the *citrus aurantium*. When recently prepared it is yellow; but when exposed for two hours to the rays of the sun, or for a longer time to diffuse daylight, it becomes of a yellowish-red. It is very fluid, lighter than water, and has a most agreeable smell. The aqueous solution known under the name of orange-flower water, is used as a perfume. It is obtained either by dissolving the oil in water, or by distilling with water the leaves either fresh or salted; the first being the stronger, but the last being the more fragrant preparation. Orange-flower water obtained by distillation, contains besides the oil, a principle which comes over with it, of a nature hitherto unknown; it possesses the property of imparting to water the faculty of becoming red with a few drops of sulphuric acid. The water formed from the oil alone, is destitute of this property. The intensity of the rose color is a test in some measure of the richness of the water in oil.

The oil of parsley is extracted from the *apium petroselinum*. It is of a pale yellow

color, having the smell of the plant, and consists of two oils separable by agitation in water. Its liquid part floats upon the surface in a very fluid form; its steareness, which falls to the bottom, is butyaceous and crystallizes at a low temperature. This concrete oil melts at 86° F.

The oil of pepper is extracted from the *piper nigrum*. In the recent state it is limpid and colorless, but by keeping it becomes yellow. It swims upon the surface of water. In odor it resembles pepper, but is devoid of its hot taste.

The oil of peppermint is extracted from the *mentha piperita*. It is yellowish, and endued with a very acrid burning taste. Its specific gravity is 0.920. At 6° or 7° below 0° F., it deposits small capillary crystals. After long keeping it affords a steareness resembling camphor, provided the oil had been obtained from the dry plant gathered in flower, but not from distillation of the fresh plant. When artificially cooled, it yields 6 per cent. of steareness, which crystallizes in prisms with three sides, has an acrid, somewhat rank taste, is soluble in ether and alcohol, and is thrown down from the latter solution by water in the form of a white powder. Peppermint water is characterized by the sensation of coolness which it diffuses in the mouth.

The oil of pimento is extracted from the envelopes of the fruits of the *myrtus pimenta*, which afford 8 per cent. of it. It is yellowish, almost colorless, of a smell analogous to that of cloves, an acrid burning taste, and a specific gravity greater than water. Nitric acid makes it first red, and after the effervescence, of a rusty brown hue. It combines with the salifiable bases, like oil of cloves.

The oil of rhodium is extracted from the wood of the *convolvulus scoparius*. It is very fluid, and has a yellow color, which in time becomes red. It has somewhat of the rose odor, and is used to adulterate the genuine otto. Its taste is bitter and aromatic, which it imparts to the otto as well as its fluidity.

The oil of roses, called also the attar or otto, is extracted by distillation from the petals of the *rosa centifolia* and *sempervirens*. Our native roses furnish such small quantities of the oil, that they are not worth distilling for the purpose. The best way of operating is to return the distilled water repeatedly upon fresh petals, and eventually to cool the saturated water with ice; whereby a little butyaceous oil is deposited. But the oil thus obtained has not a very agreeable odor, being injured by the action of the air in the repeated distillations. In the East Indies, the attar is obtained by stratifying rose leaves in earthen pans in alternate layers, with the oleiferous seeds of a species of digitalis, called *gengeli*, for several days, in a cool situation. The fat oil of the seed absorbs the essential oil of the rose. By repeating this process with fresh leaves and the same seed, this becomes eventually swollen, and being then expressed furnishes the oil. The turbid liquid thus obtained is left at rest, in well-closed vessels, where it gets clarified. The layer of oil that floats on the top is then drawn off by a capillary cotton wick, and subjected to distillation along with water, whereby the volatile otto is separated from the fat seed-oil.

The oil of roses is colorless, and possesses the smell of roses, which is not however agreeable, unless when diffused, for in its concentrated state it is far from pleasant to the nostrils, and is apt to occasion headaches. Its taste is bland and sweetish. It is lighter than water, and at the temperature of 92°, its specific gravity compared to that of water at 60° is 0.832. At lower temperatures it becomes concrete and butyaceous; and afterwards fuses at 90°. It is but slightly soluble in alcohol; 1000 parts of this liquid at 0.806 dissolving only 7½ parts at 58° F. This oil consists of two parts, the steareness and oleiessence; the latter being the more volatile odoriferous portion.

The oil of rosemary is extracted from the *rosmarinus officinalis*. It is as limpid as water, has the smell of the plant, and in other respects resembles oil of turpentine. The oil found in commerce has a specific gravity of 0.911, which becomes 0.8886 by rectification. It boils at 320° F. (occasionally at 329°). It is soluble in all portions in alcohol of 0.830. When kept in imperfectly closed vessels, it deposits a steareness to the amount of one tenth of its weight, resembling camphor. It is sometimes adulterated with oil of turpentine, a fraud easily detected by adding anhydrous alcohol, which dissolves only the oil of rosemary.

The oil of saffron is extracted from the *stigmata* of the *crocus sativus*. It is yellow, very fluid, falls to the bottom of water, diffuses the penetrating odor of the plant, and has an acrid and bitter taste. It is narcotic.

The oil of sassafras is extracted from the woody root of the *laurus sassafras*. It is colorless, but at the end of a certain time it becomes yellow or red. It has a peculiar, sweetish, pretty agreeable, but somewhat burning taste. Its specific gravity is 1.094. According to Bonastre, this oil separates by agitation with water into an oil lighter and

an oil heavier than this fluid. When long kept, it deposits a stearssence in transparent and colorless crystals, which have the smell and taste of the liquid oil.

The oil of *savine* is extracted from the leaves of the *juniperus sabina*. It is limpid, and has the odor and taste of the plant, which is one more productive of volatile oil than any other.

The oil of *tansy* has a specific gravity of 0.946, the penetrating odor of the *tanacetum vulgare*, with an acrid and bitter taste.

Oil of *turpentine*, commonly called essence of turpentine. It is extracted from several species of turpentine, a semi-liquid resinous substance which exudes from certain trees of the *pine* tribe, and is obtained by distilling the resin along with water. This oil is the cheapest of all the volatile species, and, as commonly sold, contains a little resin, from which it may be freed by re-distillation with water. It is colorless, limpid, very fluid, and has a very peculiar smell. Its specific gravity at 60° is 0.872; that of the spirit on sale in the shops is 0.876. This oil always reddens litmus paper, because it contains a little succinic acid.

100 parts of spirits of wine, of specific gravity 0.84, dissolve only 13½ of oil of turpentine at 72° F. When agitated with alcohol at 0.830 the oil retains afterwards one fifth of its bulk of the spirit; hence this proposed method for purifying oil of turpentine is defective. The oil, if left during four months in contact with air, is capable of absorbing 20 times its bulk of oxygen gas. One volume of rectified oil of turpentine absorbs at the temperature of 72°, and under the common atmospheric pressure, 163 times its volume of muriatic acid gas, provided the vessel be kept cool with ice. This mixture being allowed to repose for 24 hours, produces out of the oil from 26 to 47 per cent. of a white crystalline substance, which subsides to the bottom of a brown, smoking, translucent liquor. Others say that 100 parts of oil of turpentine yield 110 of this crystalline matter, which was called by Kind, its discoverer, artificial camphor, from its resemblance in smell and appearance to this substance. Both the solid and the liquid are combinations of muriatic acid and oil of turpentine; indicating the existence of a stearine and an oleine in the latter substance. The liquid compound is lighter than water, and is not decomposed by it, nor does it furnish any more solid matter when more muriatic gas is passed through it. The solid compound, after being washed first with water containing a little carbonate of soda, then with pure water, and finally purified by sublimation with the chalk, lime, ashes, or charcoal, appears as a white, translucent, crystalline body, in the form of flexible, tenacious needles. It swims upon the surface of water, diffuses a faint smell of camphor, commonly mixed with that of oil of turpentine, and has rather an aromatic than a camphorated taste. It does not redden litmus paper. Water dissolves a very minute quantity; but cold alcohol of 0.806 dissolves fully one third of its weight, and hot much more, depositing, as it cools, this excess in the form of crystals. The solution is not precipitated by nitrate of silver, which shows that the nature of the muriatic acid is perfectly masked by the combination. It is composed, in 100 parts, of carbon, 9.6 hydrogen, and 14 muriatic acid. The muriatic acid, or chlorine, may be separated by distilling an alcoholic solution of the artificial camphor 12 or 14 times in succession with slaked lime.

Oil of turpentine is best preserved in casks enclosed within others, with water between two. Its principal use is for making varnishes, and as a remedy for the tape-worm.

The oil of *thyme* is extracted from the *thymus serpyllum*. It is reddish yellow, has an agreeable smell, and, after being long kept, it lets fall a crystalline stearssence. It is used merely as a perfume.

The oil of *wormwood* is extracted from the *artemisia absinthium*. It is yellow, or sometimes green, and possesses the odor of the plant. Its taste resembles that of wormwood, but without its bitterness. Its specific gravity is 0.9703, according to Brisson, and 0.9725, according to Brandes. It detonates with iodine when it is fresh. Treated with nitric acid of 1.25 specific gravity, it becomes first blue, and after some time brown.

The numerous uses of unctuous oils give importance to their preparation, as articles of food, or for burning in lamps, and for the manufacture of soaps, &c. The seeds most productive of oil are those of colza (a species of cabbage, *brassica arvensis*), rape, mustard, sesamum, poppy, linseed, hemp, and beech mast. Nuts afford an oil that is much esteemed for certain purposes, and may be easily obtained by pressure. The following Table indicates the quantities of oil which can be extracted from different fruits, and some other substances:—

100 Parts of each

	Oil per Cent.	100 Parts of each.	Oil per Cent.
Walnuts	40 to 70	Wild mustard seed -	30
(Castor oil) seeds	62	Camelina seed	28

The following table is given by M. Dumas, as exhibiting the physical properties of French seed oil manufacturers:—

Summer colza	Winter colza	Rape seed	Weight per hectolitre
36 to 40	36 to 40	36 to 40	
30 to 36	30 to 36	30 to 36	
30	30	30	

	Weight per Hectolitre.	Produce in 4 days
Summer colza	54 to 63 kilogs.	
Winter colza	58 to 70 "	
Rape-seed	53 to 68 "	27 to 33
Camelina-seed	53 to 60 "	23 to 29
Poppy-seed	54 to 62 "	23 to 29
Madia Sativa	40 to 50 "	30 to 34
Beechnut	42 to 50 "	22 to 23
Hemp-seed	42 to 50 "	12 to 13
Linseed	By sample, 67.	12 to 13
Stripped walnuts	From 100 kilogs.	12 to 13
Sweet almonds	— 100 —	10 to 12
Olive	— 100 —	40 to 48

Colza, rape-seed, and cameline oils are employed for lamps; poppy, madia, safflower, linseed for painting, soft soaps, and for printers' ink; walnut oil, for food, painting, and lamps; olive oil, for food, soaps, lamps.

In extracting oil from seeds, two processes are required—1st, *trituration*; 2d, *expression*; and the steps are as follows:—

1. Bruising under revolving heavy-edge millstones, in a circular bed, or trough of iron, bedded on granite.
2. First pressure or crushing of the seeds, either of a naked fire or of steam.
3. Second crushing of the seeds, either by wedges, screw, or hydraulic presses.
4. Heating the bruised cakes; and 5. A final crushing.
6. The seeds are now very generally crushed, first of all between two iron cylinders revolving in opposite directions, and fed in from a hopper above them; after which they are rolled completely to the triturating action of the edge stones, which are usually of diameter, and 25 or 30 inches thick, weighing from 7 to 8 tons, and revolve at first, but to triturate the cakes after they have been crushed to this point, but this practice requires great care, as the heated seeds become suddenly set.

Sweet almonds - - -	— 100 —	44 to 48
Olives - - -	— 100 —	10 to 12

Colza, rape-seed, and camelina oils are employed for lamps; poppy, *madia sativa*, and linseed for painting, soft soaps, and for printers' ink; walnut oil, for food, painting, and lamps; olive oil, for food, soaps, lamps.

In extracting oil from seeds, two processes are required—1st, *trituration*; 2d, *expression*; and the steps are as follows:—

1. Bruising under revolving heavy-edge millstones, in a circular bed, or trough of iron, bedded on granite.
2. Heating of the bruised seeds, by the heat either of a naked fire or of steam.
3. First pressure or crushing of the seeds, either by wedges, screw, or hydraulic presses.
4. Second crushing of the seed cakes of the first pressure.
5. Heating the bruised cakes; and 6. A final crushing.

The seeds are now very generally crushed, first of all between two iron cylinders revolving in opposite directions, and fed in from a hopper above them; after which they yield more completely to the trituration action of the edge stones, which are usually hooped round with a massive iron ring. A pair of edge millstones of about 7 or 8 feet in diameter, and 25 or 26 inches thick, weighing from 7 to 8 tons, can crush, in 12 hours, from 2½ to 3 tons of seeds. The edge-millstones serve not merely to grind the seeds at first, but to triturate the cakes after they have been crushed in the press. Old dry seeds sometimes require to be sprinkled with a little water to make them come more freely away; but this practice requires great care.

The apparatus for heating the bruised seeds consists usually of cast iron or copper

is, with stirrers moved by machinery. *Figs. 1016 1017 1018 1019* represent the heaters naked fire, as mounted in Messrs. Maudsley and Field's excellent seed crushing

is, on the wedge or Dutch plan.

Fig. 1016 is an elevation, or side view of the fireplace of a naked heater; *fig. 1017* plan, in the line UU of *fig. 1016* *Fig. 1018* is an elevation and section parallel to line VV of *fig. 1017* *Fig. 1019* is a plan of the furnace, taken above the grate fireplace.

A, fireplace shut at top by the cast-iron plate B; called the fireplate.

C, iron ring-pan, resting on the plate B, for holding the seeds; which is kept in its place by the pins or bolts a.

D, funnels, *britchen*, into which by pulling the ring-case c, by the handles b, b, the seeds are made to fall, from which they pass into bags suspended to the hooks c.

E, *fig. 1018* the stirrer which prevents the seeds from being burned by continued contact with the hot plate. It is attached by a turning-joint to the collar F, which runs with the shaft G, and slides up and down upon it. H, a bevel wheel, in gear with the bevel wheel I, and giving motion to the shaft G.

K, a lever for lifting up the agitator or stirrer E. a, a catch for holding up the lever K, when it has been raised to a proper height.

Fig. 1020 front elevation of the wedge seed-crushing machine, or wedge-press.
Fig. 1021 section, in the line XX, of fig. 1022.

Fig. 1022 horizontal section, in the line YY, of fig. 1021.

A, A, Upright guides, or frame-work of wood.

B, B, Side guide-rails.

D, Driving stamper of wood which presses out the oil; C, spring stamper, or relieving wedge to permit the bag to be taken out when sufficiently pressed. E is the lifting shaft, having rollers, *b, b, b, b*, fig. 1021 which lift the stampers by the cams, *a, a*, fig. 1021. F, is the shaft from the power-engine, on which the lifters are fixed.

G, is the cast iron press-box, in which the bags of seed are placed for pressure, 'a'ually by the force of the wedge.

o, figs. 1019 and 1023 the spring, or relieving wedge.

e, lighter rail; *d*, lifting-rope to ditto.

f, f, f, f, flooring overhead.

g, figs. 1019 and 1023; the back iron, or end-plate minutely perforated.

h, the horse-hair bags (called hairs), containing the flannel bag, charged with seed, *i*, the dam-block; *m*, the spring wedge.

Fig. 1022 A, upright guides; C, and D, spring and driving stampers; E, lifting roller; F, lifting shaft; *a*, *a*, cams of stampers.

Fig. 1023 a view of one set of the wedge-boxes, or presses; supposing the front of them to be removed.

Fig. 1023; *o*, driving wedge; *g*, back iron; *h*, hairs; *i*, dam-block; *k*, speering or oblique block, between the two stampers; *l*, ditto; *n*, ditto; *m*, spring wedge.

When in the course of a few minutes the bruised seeds are sufficiently heated in the pans, the double door FF is withdrawn, and they are received in the bags, below the aperture G. These bags are made of strong twilled woollen cloth, woven on purpose. They are then wrapped in a hair-cloth, lined with leather.

The first pressure requires only a dozen blows of the stamper, after which the pouches are left alone for a few minutes till the oil has had time to flow out; in which interval the workmen prepare fresh bags. The former are then unlocked, by making the stamper fall upon the loosening wedge or key, *m*.

The weight of the stampers is usually from 500 to 600 pounds; and the height from which they fall upon the wedges is from 16 to 21 inches.

Such a mill as that now described, can produce a pressure of from 50 to 75 tons upon each cake of the following dimensions: 8 inches in the broader base, 7 inches in the narrower, 18 inches in the height; altogether nearly 140 square inches in surface, and about $\frac{1}{2}$ of an inch thick.

OILS, ADULTERATION OF. M. Heidenreich has found in the application of a few drops of sulphuric acid to a film of oil, upon a glass plate, a means of ascertaining its purity. The glass plate should be laid upon a sheet of white paper, and a drop of the acid let fall on the middle of ten drops of the oil to be tried.

With the oil of *rape-seed* and *turnip-seed*, a greenish blue ring is gradually formed at a certain distance from the acid, and some yellowish brown bands proceed from the centre.

With oil of *black mustard*, in double the above quantity, also a bluish green color.

With *whale* and *cod-oil*, a peculiar centrifugal motion, then a red color, increasing gradually in intensity; and after sometime, it becomes violet on the edges.

With oil of *camelina*, a red color, passing into bright yellow.

Olive-oil, pale yellow, into yellowish green.

Oil of poppies and *sweet almonds*, canary yellow, passing into an opaque yellow.

Of linseed, a brown magma, becoming black.

Of tallow or *oleine*, a brown color.

In testing oils, a sample of the oil imagined to be present should be placed alongside of the actual oil, and both be compared in their reactions with the acid. A good way of approximating to the knowledge of an oil is by heating it, when its peculiar odor becomes more sensible.

Specific gravity is also a good criterion. The following table is given by M. Heidenreich:—

	Sp. Gr.	Gay-Lussac's Alcoholm.
Oleine or Tallow Oil - - - -	0.9003	66
Oil of Turnip Seed - - - -	0.9128	60.75
Rape Oil - - - -	0.9136	60.20
Olive Oil - - - -	0.9176	58.40
Purified Whale Oil - - - -	0.9231	55.80
Oil of Poppies - - - -	0.9243	55.25
Oil of Camelina - - - -	0.9252	54.75
Linseed Oil - - - -	0.9347	50
Castor Oil - - - -	0.9611	33.75

M. Laurot, a Parisian chemist, finds that colza oil (analogous to rapeseed oil) may be tested for sophistication with cheaper vegetable oils by the increase of density

which it therefrom acquires, and which becomes very evident when the several oils are heated to the same pitch. The instrument, which he calls an *oleometer*, is merely a hydrometer, with a very slender stem. He plunges it into a tin cylinder, filled with the oil, and sets this cylinder in another containing boiling water. His *oleometer* is so graduated as to sink to zero in pure colza oil so heated; and he finds that it stops at 210° in linseed oil, at 124° in poppy-seed oil, at 83° in fish oil, and at 136° in hempseed oil—all of the same temperature. By the increase of density, therefore, or the ascent of the stem of the hydrometer in any kind of colza oil, he can infer its degree of adulteration.

The presence of a fish oil in a vegetable oil is readily ascertained by agitation with a little chlorine gas, which blackens the fish oil, but has little or no effect upon the vegetable oil.

I find that lard oil, and also hogs' lard, are not at all darkened by chlorine.

A specific gravity, bottle or globe, having a capillary tube-stopper, would make an excellent *oleometer*, on the above principle. The vessel should be filled with the oil, and exposed to the heat of boiling water, or steam at 212° , till it acquires that temperature, and then weighed. The vessel with the pure colza oil will weigh several grains less than with the other oils similarly treated. Such an instrument would serve to detect the smallest adulterations of sperm oil. Its specific gravity at 60° when pure is only 0.875; that of southern whale oil is 0.922, or 0.925; and hence their mixture will give a specific gravity intermediate, according to the proportion in the mixture. Thus I have been enabled to detect sperm oil in pretended lard oil, in my examination of oils for the customs.

OILS ESSENTIAL, Tests of Purity. 1. *Ol. Amygdalarum amar.* (*Bitter Almonds*). This oil possesses, besides its *specific gravity* and *peculiar smell*, so many striking chemical characteristics, that any adulteration of it must be easily detected. To these characteristics belong its great clear solubility in *sulphuric acid*, with a reddish brown coloration and *without any visible decomposition*; the *very slow* action which *nitric acid* has upon it, without either of the two substances undergoing any change in its physical properties; the *only partial* slow solution of *iodine* without further reaction; the indifference to *chromate of potash*; the elimination of crystals from its solution in an *alcoholic solution of caustic potash*; the peculiar inspissation by *caustic ammonia* and *muric acid*, and the elimination of crystals from the alcoholic solution of these new compounds, and lastly, the decidedly *acid reaction*; in short, almost by every reagent some peculiarity of this oil is displayed, by which its purity can be perfectly and easily established.

2. *Ol. Caryophyllorum* (*Cloves*). The properties which this oil possesses afford great opportunity of discovering its purity. Firstly, its relation to the *alcoholic solution of caustic potash*, with which it congeals entirely into a crystalline mass, *totally losing at the same time the clove odour*. Any foreign substance present would be excluded from this compound, or would interrupt and weaken it. Similar to this, and equally marked, is the butyrateous coagulum, which is obtained by shaking the oil with a solution of *caustic ammonia*, and which, after fusion, crystallizes. The *spontaneous* ready decomposition by *nitric acid*, and simultaneous formation of a reddish brown solid mass, as also the dark blue coloration of the oil by a small quantity of *sulphuric acid*, whilst a greater portion of the latter changes the oil into a blood red solid mass, are equally striking tests. To these we may add the *perfect decomposition* of the oil into brown flakes by *chromate of potash*, accompanied by the *loss of the yellow colour* of the solution of this salt; the solubility of *iodine*, which forms with it a *liquid extract*, with but a small increase of temperature, and also the *perfect* and easy solubility of santaline in it.

3. *Ol. Cinnamomi* (*Cinnamon*). With this oil the question is not merely to detect an adulteration with other oils, but also to distinguish the two sorts of this oil from one another, viz., the Ceylon oil (*oleum cinnamomi verum*) and the Chinese oil (*oleum cassia*) which differ very much in price. In both cases it is difficult to obtain accurate tests of the properties of these oils, as they are almost exclusively obtained by way of commerce, and vary considerably in their qualities, on account of their age and careless method of preparation. The chief distinction between the two oils is the *odour*: the Ceylon oil is, moreover, more liquid, and of a less specific weight than the Chinese, and may be exposed to a greater degree of cold than the latter without becoming turbid. The most distinguishing characteristic of the cinnamon oils is, perhaps, their relation to the alcoholic solution of caustic potash: both dissolve in it readily and *clear*, with a reddish yellowish brown colour; after some time, however, the solution becomes *very turbid*, and a rather heavy undissolved oil precipitates, whilst the solution gradually becomes clear again.

Another peculiar character is, where the oil is being decomposed by *nitric acid* a smell of bitter almond oil is perceptible. Both oils are at the same time converted into a brown balsam; in the Ceylon oil a brisk decomposition occurs sooner, and at a slighter heat.

Iodine dissolves rapidly in the Ceylon oil with a considerable increase of heat, and a slight expulsive movement, a tough extract-like substance remaining behind. With the Chinese oil the reaction is slow, the development of heat but very slight, quiet, and the residue a soft or liquid substance.

Chromate of potash decomposes partially the Ceylon oil into brown flakes, which are suspended in the solution. This is deprived of its yellow colour, whilst the undecomposed portion of the oil assumes a yellowish light red colour, and becomes thick. The solution treated with Chinese oil does not entirely lose its yellow colour, contains no flakes, and the oil, turbid, emulsive-like, does not become clear again.

Sulphuric acid also furnishes a good test for these oils; the Ceylon oil forms with it a solid hard mass, changing from a brownish-green into deep black; in the Chinese oil, this substance is softer, and deep olive green. A smaller quantity of acid colours the oils purple-red, whilst muriatic acid imparts to them a violet colour.

4. *Ol. Sassafras* (Sassafras.) This oil is distinguished from most other oils by the clear solution produced by iodine without inspissation. The green colour, which is at first produced by two parts of oil and one part sulphuric acid, is not produced by any other oil; by heat, this colour changes to blood-red. A greater quantity of oil produces in the heated acid a magnificent amaranth red colour, whilst the oil itself appears only brownish or bluish red. With nitric acid the decomposition takes place without heat, and reddish brown resin is formed, which on being heated becomes hard and brittle. The great specific gravity and the low degree of solubility in alcohol will easily lead to the detection of an admixture of the latter which would counteract these properties.

5. *Ol. Anisi Stellati* (Star Anise.) This oil participates in many properties of those oils of the umbelliferae which contain much stearoptene. Its combination with iodine, which takes place with a less development of vapour and heat, congeals into a solid resinous substance. By sulphuric acid this oil also easily becomes inspissated, is changed into a solid mass, and becomes by heat dark blood-red. Nitric acid, however, produces only a thick fluid balsam, whilst the oil becomes yellow, and by heat reddish-brown. The difficulty with which the oil is dissolved in five or six parts of alcohol, and in the alcoholic solution of potash, with slight coloration, as also its relation to cold, are useful tests.

6. *Ol. Anisi vulgaris* (common Anise). The constant specific gravity of the oil anisi (from 0.97 to 0.99, and still more frequently from 0.98 to 0.99), as well as its disposition to congeal readily at below a medium temperature, are good tests for this oil. But still more so is its quick congelation into a solid hard mass with iodine, accompanied with a perceptible increase of heat, and the development of yellowish-red and gray vapours. Sulphuric acid heated with the oil, produces a beautiful purple-red colour, and quickly inspissates and hardens it. The other reactions are similar to those of oil of star anise and will, combined with those here mentioned, sufficiently characterize this oil.

7. *Ol. Ruta* (Rue). The high price and strong smell of this oil lead to and facilitate its adulteration. If prepared in the laboratory, this oil is distinguished by being slowly dissolved by iodine, unaccompanied by any external signs of reaction, and the formation of slightly viscid liquid; by this means adulterations with oils of coniferae, aurantiaceae, and most labiate can be detected in it. Nitric acid acts but slowly on it, and changes it into a greenish yellow thin liquid balsam; chromate of potash produces no reaction. By the turbid solution in alcohol, by the reddish brown solution in liquor potassae, and by the similar but darker coloration which the oil and the acid assume by sulphuric acid, the cheaper oils of the labiate may be easily detected in it. The commercial compared with these characteristics appeared to be only an adulterated one.

8. *Ol. Cajuputi* (Cajuput). Omitting the tests for less frequently occurring adulterations of this oil, I confine myself to mentioning only those tests of its purity which are the result of my experiments, chiefly with regard to the rectified oil, which alone ought to be employed for medical purposes.

The first of these is the nature of the residue, resulting from the reaction of iodine after a slightly energetic reciprocal action, during which the temperature was but little increased and the development of yellowish-red vapours but slight (in another crude oil no such development took place), the residue becomes immediately inspissated into a loose coagulum, which is soon changed into a dry greenish-brown brittle mass. Fulminating oils are therefore easily detected, also the more energetically acting oils of the labiate; viz. ol. lavendul. spireae origani. But also the less violently acting oils of labiate, such as ol. rosmarini, which serves most frequently for adulteration, but which are distinguished by the energetic action of a solution of iodine, can be recognised by the degree of energy with which this reaction takes place; all, however, would materially alter the nature of the residue of the iodine test above described. The ol. rosmarini manifests under certain circumstances, also, some coagulating solid parts in its residue, but which always has the consistency of a soft extract.

The slight changes of colour which are produced by chromate of potash, are some-

what more marked with the ol. *rorismarini*, but the equally slight colour of the solution in liquor potassæ, which is clear in the cold and turbid when warm, is the same in the ol. *rorismarini*. The latter oil could not be detected by the *sulphuric acid* test; the latter assumes a deep red yellowish colour, and the oil becomes brownish; by this, however, many other adulterations may be indicated. The weak colorations of the ol. *cajeputi* by *nitric acid*, which imparts only a reddish and brownish colour, accompanied by a violent reaction and formation of a liquid balsam, will easily distinguish it from some other oils, but not from ol. *rorismarini*. Its relation to iodine is, therefore, the safest test: it can also be recognized by a sensation of cold which it leaves behind in the mouth. Its specific gravity being below 0.91 to 0.92, will show the presence of lighter oils and alcohol, and a divided rectification, and its relation to water will detect the adulteration with camphor.

9. *Ol. Mentha Piperita* (Peppermint).—Any adulteration of this oil, except with alcohol or other mint oils, could be easily detected by the peculiar smell and taste of this oil. The presence of alcohol is betrayed by the specific gravity, which is seldom under 0.90, and which must be considerably lower if the alcohol be stronger. Of the other mint oils we certainly are only acquainted with that of *M. crispata* and *crispata*; we may, however, conclude from the deviating relation of the ol. *mentha piperita* to *chromate of potash* and to *iodine*, that the other sorts differ from it chemically, as well as the plants from which they are obtained differ from one another in smell.

The most distinguishing character, which the peppermint oil shares with *no other oil of the labiata*, though with some of the *compositæ*, is its relation to *chromate of potash*, which communicates to it a *deep red brown colour*, and inspissates it into a coagulum more like an extract than a resin, and by motion is divided into a flaky form, whilst the solution of the salt soon loses the whole of its yellow colour, or appears yellowish-green.

The purple red colour imparted to the oil by the fourth part of its volume of *nitric acid*, is, at least for the qualities of 0.89 to 0.90, very characteristic. The other oils, which become merely brown, show at least a tendency to red, but all, upon an addition of acid at a higher temperature, change to a reddish-brown, and into a liquid balsam.

Mr. B. Sandrock of Hamburg, states that American oil of peppermint is adulterated with oil of turpentine, which appears to be the product of some other species of *pinus* than ours. He has frequently rectified quantities of from 80 to 100 lbs. of the American oil, in which the smell of oil of turpentine was distinctly perceived; but not to such a degree as would be the case if common oil of turpentine had been employed.

Several samples of English oil of peppermint were found by the author to be mixed with this American oil of peppermint, the price of which is only five or six marks per pound. Bley has also perceived this smell of turpentine in the oil of peppermint. The smell, however, is no certain criterion in this case, and the adulteration is better discovered by the relation to iodine and alcohol, and by the specific gravity. Pure English oil of peppermint has a specific gravity of 0.910 to 0.920; it does not explode with iodine, but forms with it a homogeneous mass, and is soluble in its own weight of alcohol.

The American oil, in which a great proportion of oil of turpentine is supposed to be contained, is sold by the name of *crude oil*, in tin bottles of twenty pounds. It is of a yellowish colour, very resinous, often as thick as oil of bitter almonds, and has a strong accessory odour of oil of turpentine. Its specific gravity is 0.855 to 0.859. When distilled with water, half of it passes over with equal parts of water, then the proportion of the water increases, and with the last yellow, somewhat thicker parts of the oil are distilled over, but with difficulty. About five-sixths of the crude oil are obtained perfectly clear like water. The first half of the rectified oil has a specific weight of 0.844, which increases, so that the latter portions have a specific gravity of 0.875 to 0.880. The oil retains now, as before, the smell and taste of turpentine, is only dissolved in five or six parts of alcohol, and explodes strongly with iodine. The resin which remains after the distillation amounts to about four or five per cent. of the oil, is soft, yellowish, turbid, and strongly smells of the oil. Heated for some time at a slight temperature, it changes these properties for all those of the pine resin.

10. *Ol. Thymi* (Thyme). This oil is distinguished by no peculiarity, and, in most cases where it is employed as perfume or externally, its pure and fine smell will be a sufficient criterion. By its slight reaction upon *iodine*, the adulteration with turpentine oil might be detected, whilst its stronger reaction upon *chromate of potash* would serve to detect other admixtures.

11. *Ol. Lavandula* (Lavender). This delicate oil suffers no other admixture but that of alcohol without becoming worthless, and in the inferior cheap qualities which are sold, the presence of alcohol is discoverable by the specific gravity. Of seventeen samples examined, the lowest specific gravity of the inferior oil was 0.86; that of the best

qualities, mostly 0·87 to 0·89. The peculiar character of the lavender oil by which it is distinguished, with regard to the degree, from all oils obtained from the *labiate*, is its *quick and violent fulmination* with iodine, and the entirely changed, pungent, acidobalsamic smell of the soft, extract-like residue. This character is invariably observed in all genuine oils, both commercial, and those prepared in the laboratory. The inferior, cheaper commercial sort, *does not fulminate*. An intentional addition of one-third of alcohol did not perceptibly weaken the fulmination; also, one half of alcohol did not destroy, but only weaken it: an equal volume of alcohol being added to the oil no fulmination took place, but a lively ebullition and development of yellowish-red vapours. A moderate proportion of alcohol cannot, therefore, be discovered by these reactions; for this purpose the almost indifferent relation of the pure oil to santaline is a safer guide, as that containing alcohol *dissolves the latter readily and quickly*. An adulteration with fulminating oils, which in this case cannot be detected by iodine, would be discovered by the differing relation to caustic potash. The alcoholic solution of the latter forms a clear solution with lavender oil, to which it communicates a *dark yellowish-red brown* colour, whilst the other oils are dissolved in it with difficulty, and become turbid, with but a slight coloration. Among the better tests, we may also reckon the deep reddish-brown colour produced by *sulphuric acid* accompanied by a strong inspissation, whilst the equally coloured acid has a slight shade of yellow.

12. *Ol. Cubebæ* (*Cubebæ*). This oil, which is *devoid of oxygen*, differs from others *having a similar composition* by its *viscosity* and *weak action upon iodine*, which imparts to it at the beginning of the reciprocal reaction a *violet* colour. Even absolute alcohol in large proportions, and at a high temperature, forms a solution which is *mostly clear*; equal weights produce a *very turbid* solution, throwing down flakes. The oil which is strongly clouded by *nitric acid*, becomes by heat only pale red, but is decomposed and converted into consistent resin. *Sulphuric acid* assumes a red colour, the oil becoming crimson. These characteristics will suffice for this oil, which is already difficult to be adulterated on account of its viscosity and want of colour.

13. *Ol. Bergamotæ* (*Bergamot*). The oils of the *aurantiaceæ* are in a still higher degree than the lavender oil protected by their delicate odour from adulteration, except with alcohol; on the other hand, a mixture of these oils with one another is easier effected, and detected with greater difficulty. There might, however, be but little inducement for doing this, except in the case of *ol. flor. aurant.*, which is proportionately much dearer than the others. The similarity of the respective chemical properties admits also here of no better test than the smell. The unvarying and great sp. gr. (from 0·87 to 0·88) will serve to detect any admixture of alcohol. The relation which the bergamot oil has to this solvent, shows distinctly the difference which exists between its own proportion of oxygen and that of the other oils of the same family; it is readily dissolved in alcohol, but, like the other oils, it makes, at least when fresh, the solution opaque. It is also distinguished from the lemon and orange oils, by being easily and clearly dissolved in *liquor potassæ*. This difference in its elements also is manifested in the reaction upon iodine, not so much with regard to its fulminating property, which, although weaker than in the lemon oil, is rather stronger than in the orange oil, but by the homogeneous nature of the residue, which, in the two last mentioned oils, and in all oils free of oxygen, consists of two combinations, differing in consistency. By the incapacity of dissolving santaline, this oil is, as well as the others of the same family, protected against an admixture of alcohol. One part of alcohol added to five parts of the oil is hardly able to impair the fulmination; two drops of alcohol added to three drops of oil produce certainly no real fulmination, but still a lively reciprocal action with effervescence.

14. *Ol. Copaivæ* (*Copaiva*). Small proportions of turpentine-oil cannot easily be detected in this oil, as both react in most cases in the same manner. A chief distinction is the weaker fulmination of the *ol. copaiv.*, as also the circumstance that the latter requires *double the quantity of alcohol* for its solution, which, notwithstanding, still remains turbid. Also its relation to *sulphuric acid* is somewhat different; the latter becomes yellowish brown red, but turpentine-oil lively yellowish-red.

OIL OF VITRIOL, is the old name of concentrated *SULPHURIC ACID*.

OLEATES, are saline compounds of oleic acid with the bases.

OLEFIANT GAS, is the name originally given to bi-carburetted hydrogen.

OLEIC ACID, is the acid produced by saponifying olive-oil, and then separating the base by dilute sulphuric or muriatic acid. See *FATS*, and *STEARINE*.

This acid is a large product in the manufacture of stearic acid, and has hitherto been of inferior value, as it burned very ill in lamps; but it has been found to be capable of improvement by agitation with dilute sulphuric acid, and in that state susceptible of affording a good light when the burner-tube of the lamp is kept cool by enclosing it in a perforated small plate, which prevents the flame from heating the said

burner small pipe, in which the wick is supported. Messrs. Humfrey and Wilson have patented it.

OLEINE, is the thin oily part of fats, naturally associated in them with glycerine, margarine, and stearine.

OLIBANUM is a gum-resin, used only as incense in Roman Catholic churches.

OLIVE OIL. See OILS, UNCTUOUS.

ONYX, an ornamental stone of little value; a subspecies of quartz.

OOOLITE is a species of limestone composed of globules clustered together, commonly without any visible cement or base. These vary in size from that of small pin-heads to peas; they sometimes occur in concentric layers, at others they are compact, or radiated from the centre to the circumference; in which case, the oolite is called *roogenstein* by the German mineralogists. In geology the oolitic series includes all the strata between the iron sand above and the red marl below. It is the great repository of the best architectural materials which the midland and eastern parts of England produce; it is divided into three systems:—

1. *The upper oolite*, including the argillo-calcareous Purbeck strata, which separate the iron and oolitic series; the oolitic strata of Portland, Tisbury, and Aylesbury; the calcareous sand and concretions, as of Shotover and Thame; and the argillo-calcareous formation of Kimmeridge, the oak tree of Smith.

2. *The middle oolite*; the oolitic strata associated with the coral rag; calcareous sand and grit; great Oxford clay, between the oolites of this and the following system.

3. *The lower oolite*; which contains numerous oolitic strata, occasionally subdivided by thin argillaceous beds; including the cornbrash, forest marble, schistose oolite, and sand of Stonesfield and Hinton, great oolite and inferior oolite; calcareo-silicious sand passing into the inferior oolite; great argillo-calcareous formation of lias, and lias marl, constituting the base of the whole series.

These formations occupy a zone 30 miles broad in England.

OOST, or OAST; the trivial or provincial name of the stove in which the picked hops are dried.

OPAL; an ornamental stone of moderate value. See LAPIDARY.

OPERAMETER is the name given to an apparatus patented in February, 1829, by Samuel Walker, cloth manufacturer, in the parish of Leeds. It consists of a train of toothed wheels and pinions enclosed in a box, having indexes attached to the central arbor, like the hands of a clock, and a dial plate; whereby the number of rotations of a shaft projecting from the posterior part of the box is shown. If this shaft be connected by any convenient means to the working parts of a gig mill, shearing frame, or any other machinery of that kind for dressing cloths, the number of rotations made by the operating machine will be exhibited by the indexes upon the dial plate of this apparatus. In dressing cloths, it is often found that too little or too much work has been expended upon them, in consequence of the unskilfulness or inattention of the workmen. By the use of the operameter, that evil will be avoided, as the master may regulate and prescribe beforehand by the dial the number of turns which the wheels should perform.

A similar clock-work mechanism, called a *counter*, has been for a great many years employed in the cotton factories to indicate the number of revolutions of the main shaft of the mill, and of course the quantity of yarn that might or should be spun, or of cloth that might be woven in the power looms. A common pendulum or spring clock is commonly set up alongside of the counter; and sometimes the indexes of both are regulated to go together, when the mill performs its average work.

OPIUM, is the juice which exudes from incisions made in the heads of ripe poppies, (*papaver somniferum*), rendered concrete by exposure to the air and the sun. The best opium which is found in the European markets comes from Asia Minor and Egypt; what is imported from India is reckoned inferior in quality. This is the most valuable of all the vegetable products of the gum-resin family: and very remarkable for the complexity of its chemical composition. Though examined by many able analysts, it still requires further elucidation.

Opium occurs in brown lumps of a rounded form about the size of the fist, and often larger; having their surface covered with the seeds and leaves of a species of *rumex*, for the purpose of preventing the mutual adhesion of the pieces in their semi-indurated state. These seeds are sometimes introduced into the interior of the masses to increase their weight; a fraud easily detected by cutting them across. Good opium is hard in the cold, but becomes flexible and doughy when it is worked between the hot hands. It has a characteristic smell, which by heat becomes stronger, and very offensive to the nostrils of many persons. It has a very bitter taste. Water first softens, and then reduces it to a pasty magma. Proof spirit digested upon opium forms *laudanum*, being a better solution of its active parts than can be obtained by either water or strong alcohol alone. Water distilled from it acquires its peculiar smell, but carries over no volatile oil.

Opium was analyzed by Bucholz and Braconnot, but at a period anterior to the knowledge of the alkaline properties of morphia and opian (narcotine). Bucholz found in 100 parts of it, 9.0 of resin; 30.4 of gum; 35.6 of extractive matter; 4.8 of caoutchouc; 11.4 of gluten; 2.0 of ligneous matter, as seeds, leaves, &c.; 6.8 of water and loss. John, who made his analysis more recently, obtained 2.0 parts of a rancid nauseous fat; 12.0 of a brown hard resin; 10.0 of a soft resin; 2 of an elastic substance; 12.0 of morphia and opian; 1.0 of a balsamic extract; 25.0 of extractive matter; 2.5 of the meconates of lime and magnesia; 18.5 of the epidermis of the heads of the poppy; 15 of water, salts, and odorous matter.

In the Numbers of the Quarterly Journal of Science for January and June, 1830, I published two papers upon opium and its tests, containing the results of researches made upon some porter which had been fatally dosed with that drug; for which crime, a man and his wife had been capitally punished, about a year before, in Scotland.* From the first of these papers the following extract is made:—

“Did the anodyne and soporific virtue of opium reside in one definite principle, chemical analysis might furnish a certain criterion of its powers. It has been pretty generally supposed that this desideratum is supplied by Sertürner’s discovery of morphia. Of this narcotic alkali not more than 7 parts can be extracted by the most rigid analysis from 100 of the best Turkey opium; a quantity, indeed, somewhat above the average result of many skilful chemists. Were morphia the real medicinal essence of the poppy, it should display, when administered in its active saline state of acetate, an operation on the living system commensurate in energy with the fourteen-fold concentration which the opium has undergone. But so far as may be judged from the most authentic recent trials, morphia in the acetate seems to be little, if any, stronger as a narcotic than the heterogeneous drug from which it has been eliminated. Mr. John Murray’s experiments would, in fact, prove it to be greatly weaker; for he gave 2 drachms of superacetate of morphia to a cat, without causing any poisonous disorder. This is perhaps an extreme case, and may seem to indicate either some defect in the preparation, or an uncommon tenacity of life in the animal. To the same effect Lassaigne found that a dog lived 12 hours after 36 grains of acetate of morphia in watery solution had been injected into its jugular vein. The morphia meanwhile was entirely decomposed by the vital forces, for none of it could be detected in the blood drawn from the animal at the end of that period. Now, from the effects produced by 5 grains of watery extract of opium, injected by Orfila into the veins of a dog, we may conclude that a quantity of it, equivalent to the above dose of the acetate of morphia, would have proved speedily fatal.

“Neither can we ascribe the energy of opium to the white crystalline substance called *narcotine*, or *opian*, extracted from it by the solvent agency of sulphuric ether; for Orfila assures us that these crystals may be swallowed in various forms by man, even to the amount of 2 drachms in the course of 12 hours, with impunity; and that a drachm of it dissolved in muriatic or nitric acid may be administered in the food of a dog without producing any inconvenience to the animal. It appears, however, on the same authority, that 30 grains of it dissolved in acetic or sulphuric acid caused dogs that had swallowed the dose to die under convulsions in the space of 24 hours, while the head was thrown backwards on the spine. Oil seems to be the most potent menstruum of narcotine; for 3 grains dissolved in oil readily kill a dog, whether the dose be introduced into the stomach or into the jugular vein.

“Since a bland oil thus seems to develop the peculiar force of narcotine, and since opium affords to ether, and also to ammonia, an unctuous or fatty matter, and a resin (the caoutchouc of Bucholz) to absolute alcohol, we are entitled to infer that the activity of opium is due to its state of composition, to the union of an oleate or margarate of narcotine with morphia. The meconic acid associated with this salifiable base has no narcotic power by itself, but may probably promote the activity of the morphia.”

Opian or narcotine, and morphia, may be well prepared by the following process. The watery infusion of opium being evaporated to the consistence of an extract, every 3 parts are to be diluted with one and a half parts in bulk of water, and then mixed in a retort with 20 parts of ether. As soon as 5 parts of the ether have been distilled over, the narcotic salt contained in the extract will be dissolved. The fluid contents of the retort are to be poured hot into a vessel apart, and the residuum being washed with 5 other parts of ether, they are to be added to the former. Crystals of narcotine will be obtained as the solution cools. The remaining extract is to be diluted in the retort with a little water, and the mixture set aside in a cool place. After some time, some narcotine will be found crystallized at the bottom. The supernatant liquid thus freed from narcotine being decanted off, is to be treated with caustic ammonia; and

* A country merchant travelling in a steam-boat upon the river Clyde, who had incautiously displayed a good deal of money, was poisoned with porter charged with laudanum. The contents of the dead man’s stomach were sent to me for analysis.

the precipitate thrown upon a filter. This, when well washed and dried, is to be boiled with a quantity of spirits of wine at 0.84, equal to thrice the weight of the opium employed, containing 6 parts of animal charcoal for every hundred parts of the drug. The alcoholic solution being filtered hot, affords, on cooling, colourless crystals of morphia.

This alkali may be obtained by a more direct process, without alcohol or ether. A solution of opium in vinegar is to be precipitated by ammonia; the washed precipitate is to be dissolved in dilute muriatic acid, the solution is to be boiled along with powdered bone black, filtered, and then precipitated by ammonia. This, when washed upon a filter and dried, is white morphia, which may be dissolved in hot alcohol, if fine crystals be wanted. See MORPHIA.

Analysis of Opium.—Half an ounce of the opium to be examined is cut into small pieces and bruised in a mortar with spirit of alcohol at 71°; the fluid is then expressed through linen, and the refuse washed with from 10 to 12 drachms of the same alcohol; the alcoholic solution is then to be filtered into a glass containing one drachm of spirits of ammonia. In 12 hours' time all the morphia, with some narcotine and meconate of ammonia, will have become deposited. The separation of the gritty crystals of morphia, which adhere to the sides of the vessel from the light, pointed crystals of narcotine, which for the most part float in the fluid, is to be effected by decantation, according to Guillemond, but this plan does not leave the morphia free from narcotine. In order effectually to separate the narcotine, the adhering meconate of ammonia must be removed by washing in water, and then shaking the crystals in pure ether, or better still in chloroform, by which the narcotine is readily dissolved, while the morphia remains entirely insoluble. After this treatment the morphia is left behind in rather large gritty crystals, slightly discoloured. This process may be varied by employing boiling alcohol and powdered opium, and adding the solution, still hot, to the solution of ammonia. According to Guillemond, 15 grammes of opium should yield at least 1.25 grammes or 8.33 per cent. Reich estimates 10 per cent, and others 12 per cent. The author gives the percentage of morphia which is obtained by the various processes of different experimenters, and states that the largest proportion (13.50 per cent.) is procured by the modification of Guillemond's method, now described, which he also considers the simplest and most certain for ascertaining the proportion of morphia.

The following process is recommended by Dr. Rieget for the detection of small quantities of opium. To the suspected substance, some potash is to be added, and then it is shaken with ether. A strip of white blotting paper is to be moistened with the solution, several times repeated. When dry, the paper is then to be moistened with muriatic acid, and exposed to the steam of hot water; if opium be present, the paper will be more or less coloured red.

Imported, in 1850, 126,102 lbs., in 1851, 106,113 lbs.; retained for consumption, 1850, 42,324 lbs., 1851, 50,368 lbs.; exported, 1850, 87,451 lbs., 1851, 65,640 lbs.; duty received, 1850, 2,222*l.*, 1851, 2,645*l.*

OPOBALSAM is the balsam of Peru in a dry state.

OPOPONAX is a gum-resin resembling gum ammoniac. It is occasionally used in medicine.

ORANGE DYE is given by a mixture of red and yellow dyes in various proportions. Annotto alone dyes orange; but it is a fugitive color.

ORCINE is the name of the coloring principle of the *lichen dealbatus*. The lichen dried and pulverized is to be exhausted by boiling alcohol. The solution filtered hot, lets fall in the cooling crystalline flocks, which do not belong to the coloring matter. The supernatant alcohol is to be distilled off, the residuum is to be evaporated to the consistence of an extract, and triturated with water till this liquid will dissolve no more. The aqueous solution reduced to the consistence of sirup, and left to itself in a cool place, lets fall, at the end of a few days, long brown brittle needles, which are to be freed by pressure from the mother water, and dried. That water being treated with animal charcoal, filtered and evaporated, will yield a second crop of crystals. These are orcine. Its taste is sweet and nauseous; it melts readily in a retort into a transparent liquid, and distils without undergoing any changes. It is soluble in water and alcohol. Nitric acid colors it blood-red; which color afterwards disappears. Subacetate of lead precipitates it completely. Its conversion into the archil red is effected by the action of an alkali, in contact with the air. When dissolved, for example, in ammonia, and exposed to the atmosphere, it takes a dirty brown red hue; but when the orcine is exposed to air charged with vapors of ammonia, it assumes by degrees a fine violet color. To obtain this result, the orcine in powder should be placed in a capsule, alongside of a saucer containing water of ammonia; and both should be covered by a large bell glass; whenever the orcine has acquired a dark brown cast, it must be withdrawn from under the bell, and the excess of ammonia be allowed to volatilize. As soon as the smell of ammonia is gone, the orcine is to be dis-

solved in water; and then a few drops of ammonia being poured into the brownish liquid, it assumes a magnificent reddish-violet color. Acetic acid precipitates the red lake of lichen.

ORES (*Mines*, Fr.; *Erze*, Germ.), are the mineral bodies which contain so much metal as to be worth the smelting, or being reduced by fire to the metallic state. The substances naturally combined with metals, which mask their metallic characters, are chiefly oxygen, chlorine, sulphur, phosphorus, selenium, arsenic, water, and several acids, of which the carbonic is the most common. Some metals, as gold, silver, platinum, often occur in the metallic state, either alone, or combined with other metals, constituting what are called native alloys.

I have described in the article **MINE**, the general structure of the great metallic repositories within the earth, as well as the most approved methods of bringing them to the surface; and in the article **METALLURGY**, the various mechanical and chemical operations requisite to reduce the ores into pure metals. Under each particular metal, moreover, in its alphabetical place, will be found a systematic account of its most important ores.

Relatively to the theory of the smelting of ores, the following observations may be made. It is probable that the coaly matter employed in that process is not the *immediate* agent of their reduction; but the charcoal seems first of all to be transformed by the atmospheric oxygen into the oxide of carbon; which gaseous product then surrounds and penetrates the interior substance of the oxides, with the effect of decomposing them, and carrying off their oxygen. That this is the true mode of action, is evident from the well-known facts, that bars of iron, stratified with pounded charcoal, in the steel cementation-chest, most readily absorb the carbonaceous principle to their innermost centre, while their surfaces get blistered by the expansion of carbonized gases formed within; and that an intermixture of ores and charcoal is not always necessary to reduction, but merely an interstratification of the two, without intimate contact of the particles. In this case, the carbonic acid which is generated at the lower surfaces of contact of the strata, rising up through the first bed of ignited charcoal, becomes converted into carbonic oxide; and this gaseous matter, passing up through the next layer of ore, seizes its oxygen, reduces it to metal, and is itself thereby transformed once more into carbonic acid; and so on in continual alternation. It may be laid down, however, as a general rule, that the reduction is the more rapid and complete, the more intimate the mixture of the charcoal and the metallic oxide has been, because the formation of both the carbonic acid and carbonic oxide becomes thereby more easy and direct. Indeed, the cementation of iron bars into steel will not succeed, unless the charcoal be so porous as to contain, interspersed, enough of air to favor the commencement of its conversion into the gaseous oxide; thus acting like a ferment in brewing. Hence also finely pulverized charcoal does not answer well; unless a quantity of ground iron cinder or oxide of manganese be blended with it, to afford enough of oxygen to begin the generation of carbonic oxide gas; whereby the successive transformations into acid, and oxide, are put in train.

OR-MOLU. The or-molu of the brass founder, popularly known as an imitation of red gold, is extensively used by the French workmen in metals. It is generally found in combination with grate and stove work. It is composed of a greater proportion of copper and less zinc than ordinary brass, is cleaned readily by means of acid, and is burnished with facility. To give this material the rich appearance, it is not unfrequently brightened up after "dipping" (that is cleaning in acid) by means of a scratch brush (a brush made of fine brass wire), the action of which helps to produce a very brilliant gold-like surface. It is protected from tarnish by the application of lacquer.

ORNAMENTAL BRASS CASTINGS. Brass castings are produced in sand, by means of patterns. The making of these patterns or models is a work involving no small amount of skill and knowledge; the simpler kinds are made by the ordinary workman; but in cases where figures, foliage, or animals are introduced, the eye and the hand of the artist become necessary. The object is first designed, then modelled in wax; a cast in lead is formed; it is then cast in brass and chased; this forms the pattern or model for the caster.

Ordinary globular or simple forms are readily copied; but when the human figure, animals, or foliage is introduced, the difficulty is increased. The castings can only be effected by means of false coreing, viz., hanging pieces of sand which are made up and lifted out in solid portions, before the model can be removed, and which afterwards are again introduced. An ordinary plaster cast with the seams upon it, if examined, will best explain the meaning of every square inch or compartment marked thereon, and shows when a core has been in a metal casting. To put the sand in a condition to produce a finer impression, powdered charcoal is dusted upon it, the cores being introduced, the moulds closed having been previously dried, and runners made for the in-

troduction of the metal (which is usually melted in earthen or clay crucibles, and in an air furnace, the fuel used being coke) follow and complete the operation.

ORPIMENT (Eng. and Fr., *Yellow sulphuret of arsenic*; *Opferment*, *Rauschgelb*, Germ.), occurs in indistinct crystalline particles, and sometimes in oblique rhomboidal prisms; but for the most part, in kidney and other imitative forms; it has a scaly and granular aspect; texture foliated, or radiated; fracture small granular, passing into conchoidal; splintery, opaque, shining, with a weak diamond lustre; lemon, orange, or honey yellow; sometimes green; specific gravity, 3.44 to 3.6. It is found in float rocks, in marl, clay, sand-stone, along with realgar, lead-glance, pyrites, and blende, in many parts of the world. It volatilizes at the blowpipe. It is used as a pigment.

The finest specimens come from Persia, in brilliant yellow masses, of a lamellar texture, called golden orpiment.

Artificial orpiment is manufactured chiefly in Saxony, by subliming in cast iron cucurbits, surmounted by conical cast-iron capitals, a mixture in due proportions of sulphur and arsenious acid (white arsenic). As thus obtained, it is in yellow compact opaque masses, of a glassy aspect; affording a powder of a pale yellow color. Genuine orpiment is often adulterated with an ill-made compound; which is sold in this country by the preposterous name of king's yellow. This fictitious substance is frequently nothing else than white arsenic combined with a little sulphur; and is quite soluble in water. It is therefore a deadly poison, and has been administered with criminal intentions and fatal effects. I had occasion, some years ago, to examine such a specimen of king's yellow, with which a woman had killed her child. A proper insoluble sulphuret of arsenic, like the native or the Saxon, may be prepared by transmitting sulphureted hydrogen gas through any arsenical solution. It consists of 38.05 sulphur, and 60.92 of metallic arsenic, and is not remarkably poisonous. The finest kinds of native orpiment are reserved for artists; the inferior are used for the indigo vat. They are all soluble in alkaline lyes, and in water of ammonia.

ORYCTOLOGY, is the name given by Werner to the knowledge of minerals; and is therefore synonymous with the English term Mineralogy.

OSTEOCOLLA, is the glue obtained from bones, by removing the earthy phosphates with muriatic acid, and dissolving the cartilaginous residuum in water at a temperature considerably above the boiling point, by means of a digester. It is a very indifferent article.

OSMIUM, is a metal discovered by Mr. Tennant in 1803, among the grains of native platinum. It occurs also associated with the ore of iridium. As it has not been applied to any use in the arts, I shall reserve any chemical observations that the subject may require for the article PLATINUM.

OTTO OF ROSES.—Means of determining the purity of the Otto of Roses.—*Sulphuric acid test*.—One or two drops of the oil to be tested is put into a watch-glass; the same number of drops of very concentrated sulphuric acid are added, and the two fluids mixed with a glass rod. All the oils are rendered more or less brown by this proceeding; but the otto of roses retains the purity of its odour. The oil of geranium acquires a strong and disagreeable odour, which is perfectly characteristic.

OXALATES are saline compounds of the bases with

OXALIC ACID (*Acide oxalique*, Fr.; *Sauerkleeäure*, Germ.), which is the object of a considerable chemical manufacture. It is usually prepared upon the small scale by digesting four parts of nitric acid of specific gravity 1.4, upon one part of sugar, in a glass retort; but on the large scale, in a series of salt-glazed stoneware pipkins, two thirds filled, and set in a water bath. The addition of a little sulphuric acid has been found to increase the product. 15 pounds of sugar yield fully 17 pounds of the crystalline acid. This acid exists in the juice of wood sorrel, the *oxalis acetosella*, in the state of a bi-oxalate; from which the salt is extracted as an object of commerce in Switzerland, and sold under the name of salt of sorrel, or sometimes, most incorrectly, under that of salt of lemons.

Some prefer to make oxalic acid by acting upon 4 parts of sugar, with 24 parts of nitric acid of specific gravity 1.220, heating the solution in a retort till the acid begins to decompose, and keeping it at this temperature as long as nitrous gas is disengaged. The sugar loses a portion of its carbon, which combining with the oxygen of the nitric acid, becomes carbonic acid, and escapes along with the deutoxyde of nitrogen. The remaining carbon and hydrogen of the sugar being oxydized at the expense of the nitric acid, generate a mixture of two acids, the oxalic and the malic. Whenever gas ceases to issue, the retort must be removed from the source of heat, and set aside to cool; the oxalic acid crystallizes, but the malic remains dissolved. After draining these crystals upon a filter funnel, if the brownish liquid be further evaporated, it will furnish another crop of them. The residuary mother water is generally regarded as malic acid, but it also contains both oxalic and nitric acids; and if heated with 6 parts of the latter acid, it will yield a good deal more oxalic acid at the expense of the malic. The brown crystals

now formed being, however, penetrated with nitric, as well as malic acid, must be allowed to dry and effloresce in warm dry air, whereby the nitric acid will be got rid of without injury to the oxalic. A second crystallization and efflorescence will entirely dissipate the remainder of the nitric acid, so as to afford pure oxalic acid at the third crystallization. Sugar affords, with nitric acid, a purer oxalic acid, but in smaller quantity, than saw-dust, glue, silk, hairs, and several other animal and vegetable substances.

Oxalic acid occurs in aggregated prisms when it crystallizes rapidly, but in tables of greater or less thickness when slowly formed. They lose their water of crystallization in the open air, fall into powder, and weigh 0.28 less than before; but still retain 0.14 parts of water, which the acid does not part with except in favor of another oxide, as when it is combined with oxide of lead. The effloresced acid contains 20 per cent. of water, according to Berzelius. By my analysis, the crystals consist of three prime equivalents, of water = 27, combined with one of dry oxalic acid = 36; or in 100 parts, of 42.86 of water with 57.14 of acid. The acid itself consists of 2 atoms of carbon = 12, + 3 of oxygen = 24; of which the sum is, as above stated, 36. This acid has a sharp sour taste, and sets the teeth on edge; half a pint of water, containing only 1 gr. of acid, very sensibly reddens litmus paper. Nine parts of water dissolve one part of the crystals at 60° F. and form a solution, of spec. grav. 1.045, which when swallowed acts as a deadly poison. Alcohol also dissolves this acid. It differs from all the other acid products of the vegetable kingdom, in containing no hydrogen, as I demonstrated (in my paper upon the ultimate analysis of organic bodies, published in the *Phil. Trans.* for 1822), by its giving out no muriatic acid gas, when heated in a glass tube with calomel or corrosive sublimate.

Oxalic acid is employed chiefly for certain styles of discharge in calico-printing (which see), and for whitening the leather of boot-tops. Oxalate of ammonia is an excellent reagent for detecting lime and its salts in any solution. The acid itself, or the bi-oxalate of potash, is often used for removing ink or iron-mould stains from linen.

A convenient plan of testing the value of peroxyde of manganese for bleachers, &c., originally proposed by Berthier, has been since simplified by Dr. Thomson, as follows. In a poised Florence flask weigh 600 grains of water, and 75 grains of crystallized oxalic acid; add 50 grains of the manganese, and as quickly as possible afterwards from 150 to 200 grains of concentrated sulphuric acid. Cover the mouth of the flask with paper, and leave it at rest for 24 hours. The loss of weight it has now suffered corresponds exactly to the weight of peroxide of manganese present; because the quantity of carbonic acid producible by the reaction of the oxalic acid with the peroxide is precisely equal to the weight of the peroxide, as the doctrine of chemical equivalents shows.

By exposing 100 parts by weight of dry sugar to the action of 825 parts of hot nitric acid of 1.38 specific gravity, evaporating the solution down to one-sixth of its bulk, and setting it aside to crystallize, from 58 to 60 parts of beautiful crystals of oxalic acid may be obtained, according to Schlesinger.

Oxalic acid may be produced by the action of nitric acid upon most vegetable substances, and especially from those which contain no nitrogen, such as well washed saw-dust, starch, gum, and sugar. The latter is the article generally employed, and possesses many advantages over every other material. Treacle, which is a modification of sugar, also comes within the same ranges. A very contemptible spirit of exaggeration prevails in respect to the amount of produce attainable by oxalic acid makers from a given weight of sugar. The generality of the statements is absurdly false. One cwt. of good treacle will yield about 116 lbs. of marketable oxalic acid, and the same weight of good brown sugar may be calculated to produce about 140 lbs. of acid. As a general rule, 5 cwt. of saltpetre, or an equivalent of nitrate of soda, with 2½ cwt. of sulphuric acid, will generate sufficient nitric acid to decompose 1 cwt. of good sugar, and yield, as above, 140 lbs. of fair marketable oxalic acid, free from superfluous moisture. Any hope of improvement seems directed rather to an economy of nitric acid, than to an increased production of oxalic acid from a given weight of sugar. The process is carried on either in large wooden vessels, or in small earthenware jars disposed in a water-bath, each jar having a capacity of about a gallon or less; the specific gravity of the nitric acid need not be so high when operating on the large scale, in a wooden trough, as when employing the earthenware jars. From 1.200 to 1.270 is the range; and the temperature in neither case should much exceed or fall short of 125° Fahr. The favourable symptoms are a regular and tolerably active evolution of gas without the appearance of red fumes, and a peculiar odour which only faintly recalls the smell of nitric oxide. The gases evolved consist, nevertheless, of nitric oxide and carbonic acid, but the influence of this latter gas has a remarkable effect in arresting the affinity of the nitric oxide for oxygen. So long as the carbonic acid is present, the mixture may be mingled with its own bulk of oxygen gas, without any diminution of volume, for several minutes, or the production of red fume; but the moment a little ammonia vapour is applied, so as

to condense the carbonic acid, the whole becomes of a deep orange hue. Herein lies a difficulty connected with the re-conversion of the nitric oxide into nitric acid by the action of atmospheric oxygen; and for the same reason, the employment of these gases in the manufacture of sulphuric acid has not answered the expectations of those who have tried the experiment practically. Carbonic acid would appear to possess, not simply a neutral agency in obstructing oxidation, but a negative power of preventing it. How far blowing atmospheric air through the acidulous saccharine solution, during the process of oxalic acid making, might tend to economize the consumption of nitric acid, we cannot pretend to say; but as the nitric acid really forms the chief item of expense, it is by such expedients that a saving may possibly be effected. When strong nitric acid is boiled upon sugar, in the way recommended in many chemical works, for the production of oxalic acid, a great loss of all the materials ensues; and most of the oxalic acid being peroxidized passes off as carbonic acid, leaving scarcely as much acid behind as is equivalent to half the weight of the sugar employed. This accounts for the discrepancies which have been published in this branch of manufacture.

Almost the only commercial article made from oxalic acid is the binoxalate of potash or salt of sorrel. This substance results from the decomposition of carbonate of potash by an excess of oxalic acid. The carbonate of potash is first dissolved in hot water, and the oxalic acid added until the effervescence ceases; after which a similar quantity of oxalic acid to that previously employed is thrown in, and the solution is boiled for a few minutes; and then it is set aside to crystallize. The crystals, after being drained and dried, are fit for the market.

Manufacture of Oxalic Acid. Oxalic acid is formed by the action of nitric acid on a great number of vegetable substances, such as sugar, rice, starch, washed sawdust, &c.

Sugar, either in its crystalline state, or in that of molasses or treacle, is the substance more commonly employed in the manufacture of oxalic acid.

On the addition of nitric acid to the saccharine solution and exposure to heat, a substitution of part of the oxygen of the nitric acid for the hydrogen of the sugar is effected, oxalic acid being formed, and binoxide of nitrogen evolved from the liquor. Other changes than this, however, take place: carbonic acid is often disengaged with the binoxide of nitrogen, and saccharic acid and other products remain in solution with the oxalic acid.

Instead of cane sugar or treacle, the saccharine substance formed by the action of sulphuric acid on potato or other starch (as in Mr. Nyren's process) is employed. For this purpose the potatoes are well washed, and then reduced into a fine pulp by rasping, grinding, or other suitable means; such pulp is then washed two or three times, by placing it in water and well stirring it therein, then permitting the pulp to subside, and running off the water. The pulp thus obtained is next placed in an open vessel of lead, or wood lined with lead, with as much water as will allow of the mixture being boiled freely, by means of steam passed through leaden pipes placed therein. Into the mixture of pulp and water, about 2 per cent. by weight (of the potatoes employed) of sulphuric acid is to be stirred in, which will be at the rate of from 8 to 10 per cent. of acid on the quantity of farina contained in the potatoes; the whole is now to be boiled for some hours, until the pulp of the potatoes is converted into saccharine matter, the completion of this process being readily ascertained by applying a drop of tincture of iodine to a small quantity of boiling liquor placed on the surface of a piece of glass, when, if there be any farina remaining unconverted, a purple colour will be produced. The saccharine product thus obtained is then filtered through a horse-hair cloth, after which it is carefully evaporated in any convenient vessel, until a gallon of it weighs about 14 or 14½ lbs.; it is now in a proper condition to be employed in the manufacture of oxalic acid, by the application of nitric acid, as in the case of operating from sugar or treacle. Horse-chestnuts, deprived of their outer shells, are also applicable to the manufacture of oxalic acid, when treated in the way above described for potatoes.

Instead of operating with sulphuric acid, the farina of potatoes and of chestnuts may be treated with diastase, and converted into a liquor similar to that obtained after evaporation from the farina and sulphuric acid before mentioned, using about the same proportion of diastase as before directed for sulphuric acid. In this case the liquor is made of the required strength at once, and the processes of filtration and evaporation are rendered unnecessary.

The apparatus required in the conversion of the saccharine matter (whether of cane sugar or formed of starch in the way above mentioned) into oxalic acid is very simple. Usually earthenware jars of about 2 gallons' capacity are employed, which, when charged with nitric acid and the saccharine material used, are placed in water-baths capable of holding a hundred or more of these jars. These baths are constructed of brick and lined with lead, and are heated by means of steam passed through coils of lead pipe placed therein.

Instead of earthenware jars, vessels of lead, or of wood lined with lead, may be em-

ployed in the manufacture of oxalic acid. For this purpose square open vessels, 8 ft. square and 3 ft. deep, are a convenient size, the liquor being heated by means of steam passed through a coil of lead pipe. A coil of about 48 ft. of one-inch pipe in a vessel of the size above mentioned, is sufficient to keep the liquor at the required temperature. In using these vessels, the liquor [whatever it may be] to be converted into oxalic acid is put into them together with the acid employed, and heated until the required decomposition is effected. The liquor is then drawn off by a syphon, or by a cock placed at the bottom of the vessel, into shallow leaden vessels, or wooden vessels lined with lead, to cool and crystallize, and the mother waters are drawn off from the crystals, and used in the next operation.

When the manufacture of this acid is conducted in large vessels, as above mentioned, the specific gravity of the nitric acid may be less than when the earthenware jars are used. From 1.200 to 1.270 are about the limits of the range allowed for the gravity of the acid. As regards the temperatures of the baths, this should be maintained at or about 125° Fahr. Whilst the operation is in progress, the active evolution of gas, without the appearance of red fumes, and the emission of a peculiar smell, slightly indicative of the presence of nitric oxide, are amongst the signs that every thing is in good working condition. The judicious addition of sulphuric acid is found to contribute to an increase of the quantity of oxalic acid produced. The product of acid from a given quantity of sugar has been much understated by chemical writers: this has most probably arisen from the circumstance of boiling the sugar with strong nitric acid, by which means a large quantity of oxalic acid becomes converted, as soon as formed, into carbonic acid, and the result is, that the actual product of oxalic acid obtained represents only about one-half of the sugar employed, and therefore not above one-half the quantity which should have been obtained. Thus we find it stated, that from 50 to 60 lbs. of oxalic acid are obtainable from 100 lbs. of good sugar, whereas the quantity actually obtained in practice is from 125 to 130 lbs. Treacle of course gives a smaller product; 100 lbs. of fair quality yielding from 105 to 110 lbs. of oxalic acid.

The mother liquor having been poured off, the crystals of acid obtained are thrown on drainers and washed, then carefully dried in a suitable stove. The mother liquors, when treated with a fresh supply of nitric acid and treacle, are ready for a further operation.

About 4½ cwt. of nitrate of soda, and 2½ cwt. of sulphuric acid, are used to furnish the nitric acid required to convert 1 cwt. of good sugar into oxalic acid.

Mr. Jullion has patented a process for the conversion of formic acid into oxalic acid. For this purpose, formic acid is saturated with a solution of caustic potash, and then half the quantity of caustic potash required for saturation is added to the above mixture; the whole is then evaporated to dryness, and heated to 560° Fahr. By this process, the formic acid is decomposed, and oxalate of potash formed. Caustic soda may also be employed instead of caustic potash.

The oxalate of potash or of soda thus obtained is then treated with sulphuret of barium, hydrate of baryta, or any soluble salt of baryta, whereby an oxalate of baryta is precipitated, from whence pure oxalic acid may be obtained by means of sulphuric acid.

Another mode of obtaining oxalic acid is by the process patented by Dr. Wilton Turner, who directs the uric acid obtained from guano to be treated with peroxide of lead or manganese suspended in water, at a boiling temperature, by which means it will be decomposed into oxalic acid, allantoin, urea. The oxalic acid forms an insoluble compound with the lead or manganese. The lead process is as follows: A known weight of uric acid is placed in an open cylindrical iron vessel, capable of holding two pounds of water for every pound of the acid, and adapted to boil by steam. A clear saturated solution of lime water is then added, and as soon as it is heated, and in brisk ebullition, the peroxide of lead is added in successive portions, as long as it is observed to be whitened by the boiling liquid. The whitish powder thus obtained is oxalate of lead. About 240 lbs. of peroxide of lead are required for each 168 lbs. of uric acid employed. The supernatant liquor is next drawn off, and the oxalate of lead washed with clear water; this is then boiled with dilute muriatic acid [equal parts of acid and water], by means of which oxalic acid is obtained in solution, which is evaporated and crystallized, whilst muriate of lead remains as the precipitate.

The allantoin is also decomposed into oxalic acid and ammonia by boiling it with caustic alkali. The former unites with the alkali used, while the ammonia passes over, and may be collected as liquid ammonia; the oxalic acid thus generated may be obtained as oxalate of potash, if potash be the alkali employed, or as oxalic acid if baryta be used, by decomposing the latter oxalate by means of sulphuric acid. In this case, the oxalate of baryta may be treated in the way previously described for oxalate of lead. This process is delusive.

As regards these various methods for obtaining oxalic acid, their employment will

of course always be a question of *E. & d.*, the economy of many operations of manufacturing chemistry being often dependent upon their adaptation to the requirements or purposes of particular manufactures, in connection with other branches of manufacture carried on by them.

The low price at which treacle and sugar are now obtainable is much in favour of their use in this manufacture. The chief point, however, to which attention must be directed, in order to lessen the cost of production of this article, is in economizing the nitric acid used.

In speaking of the action of nitric acid upon sugar, it was observed that carbonic acid was produced, and that it passes off with the deutoxide of nitrogen also set at liberty. The presence of carbonic acid, in this case, proves a great obstacle in the reconversion of nitric oxide into nitric acid, preventing the union of the oxygen of the air with the nitric oxide. Various processes have been from time to time suggested to effect this economy in the manufacture of oxalic acid: amongst these, the following may more particularly be noticed:—

In 1846, Mr. Jullion patented a method of converting the oxides of nitrogen given off in the manufacture of oxalic acid, into nitrous and nitric acids. For this purpose, he uses a "generating vessel," which is a vessel something like a Woulfe's bottle, only having a moveable top fitting air-tight, and capable of holding about 100 gallons. The materials to form the oxalic acid are introduced, and the vessel heated by a water-bath (by steam or other convenient means), which surrounds the vessel; a quantity of nitric acid is then added, and air or oxygen is forced in through a pipe inserted in the top. The oxygen, coming in contact with the evolved oxides of nitrogen, immediately converts a portion into nitrous and hyponitrous acids, which are partly again absorbed by the fluid in the vessel; another portion passes off by a pipe inserted in the upper part of the vessel, which pipe passes through a furnace. This part in the furnace is a little enlarged, and is heated from 600° to 900° Fahr.; this part of the pipe or tube contains spongy platinum, or other similar substances; the gases, in coming in contact with the heated platinum, combine to form nitric acid, which is afterwards condensed in vessels arranged as usual in the manufacture of this acid. Instead of platinum a close vessel containing water may be used, which decomposes hyponitrous and nitrous acids, giving rise to nitric acid. This principle is applied in the following ways:—the oxides of nitrogen, as evolved from the liquor in the decomposing vessel, coming in contact with oxygen, are converted into hyponitrous and nitrous acids, which, upon being mingled with steam, are decomposed into nitric acid and binoxide of nitrogen; or the introduction of steam may be obviated, by using heated air or oxygen in the decomposing vessels, by which means moisture will be furnished from the liquor; the amount of evaporation thus caused will also prevent an inconvenient increase of the mother-liquor. The compounds thus formed, when passed through suitable condensers, will, if the supply of atmospheric air or oxygen has been in excess, be all or nearly all condensed into nitric acid.

The following is a description of Crane and Jullion's continuous method of manufacturing oxalic acid and nitric acid at one process:—the oxalic acid mother-liquor of a previous process is placed in a close or covered vessel, termed a "generator," formed of slate; nitric acid and syrup in the usual proportions employed for such quantity of mother-liquor are also placed separately in feeding vessels, over the "generator;" heat is then applied to the mother-liquor, and the temperature raised as quickly as possible to 180° or 200° Fahr. Streams of nitric acid and syrup are then caused to flow into the generator by means of suitable stop-cocks and funnel-pipes, in such a quantity that the delivery of the whole shall occupy about 18 hours, at the expiration of which time the process will be completed.

The gases arising from the decomposition of the materials so supplied pass off through an eduction pipe in the top of the generator, into a receiver, into which a stream of chlorine is introduced (from a chlorine generator) sufficient to convert the whole of the oxides of nitrogen into nitric acid. A portion of water in the receiver is decomposed, its oxygen combining with the oxide of nitrogen to form nitric acid, whilst its hydrogen combines with the chlorine to form hydrochloric acid. These mixed vapours pass over into suitable condensing vessels placed to receive them. The whole of the nitric acid and syrup having been run in, and the liberation of the gases or oxides of nitrogen having ceased, the oxalic acid liquor is drawn off from the generator and crystallized.

Messrs. M'Dougall and Rawson have patented a method of recovering the vapours which pass off in the manufacture of oxalic acid. To effect this, they direct the employment of a series of vessels containing water, into the first of which the nitrous gas or fumes are passed, through a tube dipping below the surface of the vessel; air is also admitted, which mixes with the gas bubbling up through the water. Attached to the last vessel of the series is a pneumatic apparatus, by means of which the mixture of

nitrous gas and air are drawn through this series of vessels, each containing a tube dipping into the liquid, and another tube or pipe attached to its top to connect it with the next vessel. The nitrous gas thus passing alternately into air and water, becomes converted into nitric acid. In this process, the following reaction is said to take place:—

On 3 N O_2 being passed into water of the temperature of 100° Fahr. , or upwards, $2 \text{ N O}_2 + \text{N O}_2$ result, the 2 N O_2 , two atoms of nitric acid, remain in solution, whilst the N O_2 , which is an incondensable gas, bubbles through the liquid, and unites with the air in the vessel above the liquid; it immediately takes two atoms of oxygen from the air, and becomes N O_4 , which passing through the liquid becomes nitric acid and nitrous gas, as before, and thus nearly the whole of the nitrous fumes or gas are reconverted into nitric acid.

In Ecartot's patented process for recovering the nitric acid, he fills his regenerating vessels with a porous substance, such as pumice-stone, supplying the oxygen by a blowing machine, a flow of steam being brought from a boiler.

Rationale of the Process for Oxalic Acid.—As no accurate account of the decomposition which ensues in the manufacture of oxalic acid has yet been published, that I am aware of, the following experiments may tend perhaps to draw attention to this subject.

The apparatus employed consisted of a large glass retort, placed in a water-bath, and luted to a tubulated receiver from the opening in which a tube passed into a two-necked bottle containing a solution of ammonia; this bottle was connected by a tube with another of the same size and form containing a solution of nitrate of lime, from which an exit tube passed which dipped under water, and allowed the escape of the incondensable gaseous matter.

The temperature of the water-bath was maintained as nearly as possible at 125° Fahr. for forty-eight hours in each experiment, after which the solution of oxalic acid was set aside for two days to crystallize. The crystals were allowed to effloresce in a drying stove, so as to remove all excess of nitric acid; they were then dissolved, re-crystallized, dried and weighed.

The amount of carbonic acid was determined by mixing the solutions of ammonia, and nitrate of lime after each experiment, allowing the carbonate of lime to settle for four-and-twenty hours, after which it was washed, dried, and weighed. The sugar employed was the best refined white, and it lost nothing in weight by prolonged exposure to a temperature of 212° . The nitric acid was pure, and of specific gravity 1.245 at 60° ; it contained as nearly as possible one third of its weight of dry acid, as was proved by the amount of pure carbonate of soda which it neutralized. The following table exhibits the results of eight experiments, showing the amount of sugar and dilute nitric acid employed, and the quantity of oxalic and carbonic acids produced; the liquor from the receiver and the mother liquor of each experiment being added to the one following.

Number.	Employed.		Obtained.	
	Sugar in Ounces.	Dil. Nitric Acid in Ounces.	Oxalic Acid in Ounces.	Carbonic Acid in Ounces.
1.	28	184	$17\frac{1}{2}$	$20\frac{1}{2}$
2.	28	184	$32\frac{1}{2}$	$22\frac{1}{2}$
3.	28	184	30	21
4.	28	184	$29\frac{1}{2}$	$21\frac{1}{2}$
5.	28	184	$31\frac{1}{2}$	22
6.	28	184	$30\frac{1}{2}$	21
7.	28	184	$30\frac{1}{4}$	$21\frac{1}{2}$
8.	28	184	31	$21\frac{1}{2}$

A large quantity of mother liquor remained, from which no crystals were attempted to be obtained, as these may be set against the small produce of experiment No. 1. If then we omit that experiment altogether, we shall have an average of the seven following, showing that 196 of sugar and 1288 of diluted nitric acid have produced $214\frac{1}{2}$ of oxalic acid, and $150\frac{1}{2}$ of carbonic acid, and that the proportion of carbon in the oxalic acid obtained almost exactly equals that in the carbonic acid, and that by the action of nitric acid in the way described, one half of the carbon of any given quantity of sugar is converted into oxalic acid, and the other half into carbonic acid. I have made many experiments with nitric acid of various densities and at various temperatures, but without obtaining in any instance so large a produce of oxalic acid, as with acid of the strength indicated. When strong acid is employed, the temperature rises too high, and a quantity of formic acid is occasionally produced, which distils

over into the receiver and materially diminishes the produce of oxalic acid. From these experiments it would appear that no more than 124 lbs. of oxalic acid can be obtained from 1 cwt. of sugar. This I am aware is much below the quantity generally supposed to be produced on the large scale, and which is stated to vary from 135 to 140 lbs. for the cwt. of sugar; such acid is, however, contaminated with nitric acid and mother liquor, and is moreover decidedly damp, as shown by the manner in which the crystals cling to the sides of the bottle in which they are contained; some allowance must also be made for the tendency to exaggeration which prevails in our manufactories. These proportions do not greatly differ from those employed in practice by oxalic acid makers, when allowance is made for the loss of nitric acid incidental to their mode of manufacture. The following is the general proportion of materials employed:—

Sugar	-	-	-	-	-	112 lbs.
Nitrate of potash	-	-	-	-	-	560 lbs.
Sulphuric acid	-	-	-	-	-	280 lbs.

which are said to produce 135 lbs. of oxalic acid and 490 lbs. of sulphate of potash or sal-nitren.

Experiment has proved to me that the first change produced is to convert the cane sugar into grape sugar; and as the first portions of gas evolved consist almost entirely of nitric oxide with little or no carbonic acid, it is clear that some compound is generated in the commencement of this process, which contains the elements of sugar united to an excess of oxygen: the following diagram must therefore be looked on as merely explanatory of the ultimate change.

Of this, at least, I am sure that in some hundreds of attempts conducted on a pretty large scale, I have never once exceeded the amount here stated (124 lbs.), when the acid was properly purified and freed from adhering moisture. The following diagram, in my opinion, represents the nature of the ultimate decomposition which ensues in this manufacture, although other substances are unquestionably produced in the first instance.—*Lewis Thompson.*

Materials employed.

		Atoms.		Products.	
Common sugar, atom - 1	Carbon	- 12	6	6 Carbonic acid.	2 Water.
	Hydrogen	- 11	9		
	Oxygen	- 11	9		
Nitric acid, 7 atoms	Nitrogen	- 7	14	7 Deutoxide of Nitrogen.	3 Crystallized oxalic acid.
	Oxygen	- 35	12		

OXICHLORIDE OF LEAD. A white pigment patented by Mr. Hugh Lee Pattinson of Newcastle, which he prepares by precipitating a solution of chloride of lead in hot water with pure lime water, in equal measures; the mixture being made with agitation. As the operation of mixing the lime water, and the solution of chloride of lead, requires to be performed in an instantaneous manner, the patentee prefers to employ for this purpose two tumbling boxes of about 16 feet cubic capacity, which are charged with the two liquids, and simultaneously upset into a cistern in which oxichloride of lead is instantaneously formed, and from which the mixture flows into other cisterns, where the oxichloride subsides. This white pigment consists of one atom of chloride of lead and one atom oxide of lead, with or without an atom of water.

OXIDES, are neutral compounds, containing oxygen in equivalent proportion.

OXISELS, are salts, consisting of oxygenated acids and oxides, to distinguish them from the HALOSELS, which are salts consisting of one of the archæal elements: such as chlorine, iodine, bromine, &c., combined with metals. See SALT.

OXYGEN (*Oxigène*, Fr.; *Sauerstoff*, Germ.); can be examined only in the gaseous form, and is most conveniently obtained pure by exposing chlorate of potash, or red oxide of mercury, in a glass retort, to the heat of a spirit lamp; 100 grains of the salt yield 115 cubic inches of gas. One pound of nitre, ignited in an iron retort, gives out about 1200 cubic inches of oxygen, mixed with a little nitrogen. The peroxide of manganese alone, or mixed with a little chlorate of potash, also affords it, either by ignition alone in an iron or earthen retort, or by a lamp heat in a glass retort, when mixed with sulphuric acid. Oxygen is void of taste, colour, and smell. It possesses all the mechanical properties of the atmosphere. Its specific gravity is 1.1026 compared to air 1.0000; whence 100 cubic inches of it weigh 33.85 grains. Combustibles, even iron and diamonds, once kindled, burn in it most splendidly. It forms 21 parts in 100 by volume of air, being the constituent essential to the atmospheric functions of supporting animal and vegetable life, as well as flame. 3 parts of bichromate of

potash in powder, with 4 parts of oil of vitriol, when heated, afford oxygen gas plentifully.

The full development of this subject in its multifarious relations will be discussed in my forthcoming new system of chemistry.

OXYGENATED-MURIATIC, and OXYMURIATIC, are the names originally given by the French chemists, from false theoretical notions, to chlorine, which Sir H. Davy proved to be an undecomposed substance.

Oxygen in the atmosphere, method of determining the amount thereof. When some solution of caustic potash is conveyed into a tube filled with mercury, and then a solution of pyrogallie acid, the liquids mix without any alteration; but if now a bubble of oxygen or of air be passed into the tube, the liquid acquires a blackish red or nearly black colour, and the oxygen is as rapidly absorbed as carbonic acid by caustic potash. The quantity of oxygen which is absorbed under these circumstances by 1 part by weight of pyrogallie acid is enormous. According to the experiments of Dobereiner, 1 gramme of pyrogallie acid in an ammoniacal solution absorbs 0.38 gramme or 260 cub. centim. of oxygen; this is more than the quantity absorbed by 1 part in weight of sodium on its conversion into oxide, which only amounts to 236 cub. centim. In one experiment, which was made with especial care, a solution of 1 gramme pyrogallie acid in caustic potash (K O, Aq), in order to pass into neutral carbonate, absorbs at 32° F. 192 cub. centim. carbonic acid, the absorbent capability of pyrogallie acid for oxygen, it will be seen, is not less than that of potash for carbonic acid. The following results, which were obtained with atmospheric air, will give an idea of the accuracy which is obtained by this method:

Number.	Volume of Air after Introduction of the Caustic Potash.	Decrease in Volume after Introduction of Pyrogallie Acid.	Per cent. in Volume of Oxygen.
1.	221.5	46.5	20.99
2.	201.0	42.0	20.89
3.	193.0	40.6	21.03
4.	210.0	44.0	20.95
5.	204.5	42.5	20.77
6.	195.0	40.8	20.92
7.	200.0	41.8	20.90
8.	200.0	41.6	20.80
9.	200.0	41.5	20.75
10.	236.0	49.0	20.76
11.	258.0	54.0	20.93

With the expired air of different persons the following results were obtained, some with gallic, others with pyrogallie acid:—

No	Air.	Decrease in Volume by Solution of Potash.	Decrease in Volume by Gallic or Pyrogallie Acid.	Volume of Nitrogen.
I.	220.0	9.0	36.0	175.0
II.	221.5	9.0	36.0	175.5
III.	200.0	11.0	30.0	168.2
IV.	194.0	10.0	29.0	155.0

Consequently, the corresponding air in the experiments contains:—

	I.	II.	III.	IV.
Carbonic acid	- - - 4.09	4.06	5.5	5.41
Oxygen	- - - 16.36	16.34	15.0	14.95
Nitrogen	- - - 79.55	79.23	79.1	79.90

These analyses have only been made to test the method, and have no value in a physiological point of view.

The following was the mode of proceeding in the above mentioned analyses:—The air in which the amount of oxygen and carbonic acid was to be determined, was measured in graduated tubes over mercury. The tubes would contain about 30 cubic centim., each cubic centim. divided into 5 parts; they were filled $\frac{2}{3}$ with the air, the quantity read off, and now $\frac{1}{10}$ of its volume of solution of potash of 1.4 sp. gr. (one part dry

hydrate of potash to two parts water), introduced by means of the common pipette with curved point: by quickly moving up and down the tubes in the mercury, the solution of potash is spread over the whole inner surface of the tubes; and when no further decrease of space is perceptible, the decrease of volume is read off.

When the air has been previously dried by means of chloride of calcium, the decrease in volume accurately furnishes the amount of carbonic acid in the air; but if it were moist, the determination has an error attached to it, which is owing to the absorption of the aqueous vapour by the strong solution of potash.

After the carbonic acid has been determined, a solution of pyrogallie acid, containing one gramme of acid in 5 to 6 cub. centim. water, is introduced by means of a second pipette into the same tube, and amounting to about half the volume of the solution of potash. The same plan is adopted as in the determination of the carbonic acid, that is to say, the mixed liquids are well shaken over the inner surface of the tube, and when no further absorption is perceptible, the amount of nitrogen is measured off.

By mixing the solution of pyrogallie acid with the potash, the latter is diluted, and an error arises from the diminution of its tension; but this appears to be so exceedingly small, that it is not determinable; at the same time, it may easily be avoided, if, after the absorption of the oxygen, a piece of solid hydrate of potash, corresponding to the amount of water in the solution of pyrogallie acid, is introduced, and its solution awaited.

Ordinary gallic acid may be employed instead of the pyrogallie acid with the same result; but its employment has this inconvenience, that the absorption of the oxygen requires a much longer time, at least $1\frac{1}{2}$ to 2 hours, instead of as many minutes. Owing to the sparing solubility of gallic acid in water, it must be previously converted into gallate of potash, a cold saturated solution of which is employed. When this liquid is neutral, or contains a very slight excess of acid, it does not experience any alteration in the air. Its property of absorbing oxygen only becomes active in the presence of an excess of alkali.

When the gallic acid has been mixed with the caustic potash in the tube, the liquid on coming into contact with air containing oxygen, assumes a dark red colour; thin layers acquire almost a blood-red colour, which after a time passes into brown. By the production of this blood-red colour in the liquid, which moistens the sides of the tube on agitation, the progress of the absorption can be very distinctly traced; when this colouring is no longer exhibited, the operation is complete. With respect to the absorbent capacity of gallic acid for oxygen, it is known, from the experiments of Chevreul, that 1 gramme of gallic acid dissolved in strong potash absorbs 290 cub. centim., or nearly 0.417 gramme oxygen. In this respect it is in nowise inferior to pyrogallie acid.

Dr. Stenhouse has described a most excellent method for preparing pyrogallie acid. He obtained, by sublimation from the dry aqueous extract of the gall nuts, precisely in the same manner as benzoic acid is prepared from benzoïn resin, above 10 per cent. in sublimed acid of the weight of the extract. When those who are engaged in photography have become convinced that in many cases pyrogallie acid is preferable to gallic acid, the increased demand for this acid will render its preparation still more productive.*

The principal error in the above eudiometrical process, which is scarcely to be got rid of, is occasioned by the difficulty of accurately reading off and determining the volume of the air, and its decrease from the absorption of the carbonic acid and of the oxygen, owing to the adhesion of the liquid to the sides of the tubes. This error becomes smaller when the precaution is adopted of using nearly the same volume of air for each analysis; but though this method admits of perfectly trustworthy determinations in comparative analyses, it will not supersede the processes of MM. Dumas and Boussingault, or that of MM. Regnault and Reiset, or that of M. Bunsen for absolute determinations.

It need scarcely be mentioned, that the process described is only an application of the beautiful observations made by Chevreul and Dobereiner on gallic and pyrogallie acids, and that the merit of the discovery belongs to these illustrious individuals.

P.

PACKFONG, is the Chinese name of the alloy called white copper, or German silver.

PACO, or PACOS, is the Peruvian name of an earthy-looking ore, which consists of brown oxide of iron, with imperceptible particles of native silver disseminated through it.

* By the dry distillation of so-called Chinese galls, in small retorts capable of holding from 5 to 6 oz. in coarse fragments, a very concentrated solution of pyrogallie acid is obtained, which, evaporated on the water bath, yields of brown crystalline pyrogallie acid nearly 15 per cent. of the weight of the galls.

PADDING MACHINE (*Machine à plaquer*, Fr.; *Klatsch*, or *Grundarmaschine*, Germ.), in calico-printing, is the apparatus for imbuing a piece of cotton cloth uniformly with any mordant. In fig. 1024 *a n c d* represents in section a cast iron

convenient support. About two inches above the bottom of the trough, there is a copper dip-roller *c*, under which the cloth passes, after going round the guide roller *m*. Upon escaping from the trough, it is drawn over the half-round stretcher-bar at *i*, grooved obliquely right and left, as shown at *N*, whereby it acquires a diverging extension: from the middle, and enters with a smooth surface between the two cylinders *E F*. These are lapped round 6 or 7 times with cotton cloth, to soften and equalize their pressure. The piece of goods glides obliquely upwards, in contact with one third of the cylinder *F*, and is finally wound about the uppermost roller *H*. The gudgeon of *H* revolves in the end of the radius *h, k*, which is jointed at *k*, and moveable by a mortise at *i* along the quadrantal arc towards *l*, as the roller *K* becomes enlarged by the convolutions of the web. The under cylinder *E* receives motion by a pulley or rigger upon its opposite end, from a band connected with the driving-shaft of the printshop. To ensure perfect equability in the application of the mordant, the goods are in some works passed twice through the trough; the pressure being increased the second time by sliding the weight *g* to the end of the lever *d f*.

A view of a padding machine in connexion with the driving mechanism is given under **HOT FLOZ**; see also **STARCHING MACHINE**.

PAINT. See **ROUGE**.

PAINTS, GRINDING OF. There are many pigments, such as common orpiment,

or, king's yellow, and verdigris, which are strong poisons; others which are very deleterious, and occasion dreadful maladies, such as white lead, red lead, chrome yellow, and vermillion; none of which can be safely ground by hand with the slab and muller, but should always be triturated in a mill. The emanations of white lead cause, first, that dangerous disease the *colica pictorum*, afterwards paralysis, or premature decrepitude and lingering death.

Figs. 1025 1026 1027 1028 exhibit the construction of a good color-mill in three views;

fig. 1025 being an elevation shown upon the side of the handle, or where the power is applied to the shaft; fig. 1026 a second elevation, taken upon the side of the line *c, d*, of the plan or bird's-eye view, fig. 1027.

The frame-work *A A* of the mill is made of wood or cast iron, strongly mortised or bolted together; and strengthened by the two cross iron bars *B, P*. Fig. 1028 is a plan of the millstones. The lying or nether millstone *c*, fig. 1026 is of cast iron, and is channelled on its upper face like corn millstones. It is fixed upon the two iron bars *B, P*; but may be preferably supported upon the 3 points of adjustable screws, passing up through bearing-bars. The millstone *c* is surrounded by a large iron hoop *D*, for preventing the pasty-consisted color from running over the edge. It can escape only by the

sluice hole *x*, fig. 1026 formed in the hoop; and is then received in the tub *x* placed beneath.

The upper or moving millstone *F*, is also made of cast iron. The dotted lines indicate its shape. In the centre it has an aperture with ledges *G, G*; there is also a ledge upon its outer circumference, sufficiently high to confine the color which may occasionally accumulate upon its surface. An upright iron shaft *H* passes into the turning stone, and gives motion to it. A horizontal iron bevel wheel *K*, figs. 1026, 1027 furnished with 27 wooden teeth, is fixed upon the upper end of the upright shaft *H*. A similar bevel wheel *L*, having the same number of teeth, is placed vertically upon the horizontal iron axis *M, M*, and works into the wheel *K*. This horizontal axis *M, M* bears, at one of its ends, a handle or winch *N*, by which the workman may turn the millstone *F*; and on the other end of the same axis, the fly-wheel *O* is made fast, which serves to regulate the movements of the machine. Upon one of the spokes of the fly-wheel there is fixed, in like manner, a handle *P*, which may serve upon occasion for turning the mill. This handle may be attached at any convenient distance from the centre, by means of the slot and screw-nut *Z*.

The color to be ground is put into the hopper *N*, below which the bucket *S* is suspended, for supplying the color uniformly through the orifice in the millstone *C*. A cord or chain *T*, by means of which the bucket *S* is suspended at a proper height for pouring out the requisite quantity of color between the stones, pulls the bucket obliquely, and makes its beak rest against the square upright shaft *H*. By this means the bucket is continually agitated in such a way as to discharge more or less color, according to its degree of inclination. The copper cistern *X*, receives the color successively as it is ground; and, when full, it may be carried away by the two handles *Z, Z*; it may be emptied by the stopcock *V*, without removing the tub.

PAINTS, VITRIFIABLE. See PORCELAIN, POTTERY, and STAINED GLASS.

PALLADIUM, a rare metal, possessed of valuable properties, was discovered in 1803, by Dr. Wollaston, in native platinum. It constitutes about 1 per cent. of the Columbian ore, and from $\frac{1}{2}$ to 1 per cent. of the Uralian ore of this metal; occurring nearly pure in loose grains, of a steel-gray color, passing into silver white, and of a specific gravity of from 11.8 to 12.14; also as an alloy with gold in Brazil, and combined with selenium in the Harz near Tilkrode. Into the nitro-muriatic solution of native platinum, if a solution of cyanide of mercury be poured, the pale yellow cyanide of palladium will be thrown down, which being ignited affords the metal. This is the ingenious process of Dr. Wollaston. The palladium present in the Brazilian gold ore may be readily separated as follows: melt the ore along with two or three parts of silver, granulate the alloy, and digest it with heat in nitric acid of specific gravity 1.3. The solution containing the silver and palladium, for the gold does not dissolve, being treated with common salt or muriatic

acid, will part with all its silver in the form of a chloride. The supernatant liquor being concentrated and neutralized with ammonia, will yield a rose-colored salt in long silky crystals, the ammonia-muriate of palladium, which being washed in ice-cold water, and ignited, will afford 40 per cent. of metal.

The metal obtained by this process is purer than that by the former; and if it be fused in a crucible along with borax, by the heat of a powerful air-furnace or forge, a button of malleable and ductile palladium will be produced. When a slip of it is heated to redness, it takes a bronze-blue shade of greater or less intensity, as the slip is cooled more or less slowly; but if it be suddenly chilled, as by plunging it into water, it resumes instantly its white lustre. This curious phenomenon depending upon oxydization and de-oxydization, in different circumstances, serves at once to distinguish palladium from platinum.

Pure palladium resembles platinum, but has more of a silver hue; when planished by the hammer into a cup, such as that of M. Breant, in the museum of the Mint at Paris, it is a splendid steel-white metal, not liable, like silver, to tarnish in the air. Another cup made by M. Breant, weighing 2 lbs. (1 kilogramme), was purchased by Charles X., and is now in the *garde-meu*ble of the French crown. The specific gravity of this metal, when laminated, is stated by Dr. Wollaston at 11.8, and by Vauquelin at 12.1. It melts at from 150° to 160° Wedgewood; and does not oxydize at a white heat. When a drop of tincture of iodine is let fall upon the surface of this metal, and dissipated over a lamp flame, a black spot remains, which does not happen with platinum. A slip of palladium has been used with advantage to inlay the limbs of astronomical instruments, where the fine graduated lines are cut, because it is bright, and not liable to alteration, like silver.

There are a protoxyde and peroxyde of palladium. The proto-chloride consists of 60 of metal and 40 of chlorine; the cyanide, of 67 of metal, and 33 of cyanogen.

PALM OIL (*Huile de palme*, Fr.; *Palmöl*, Germ.), is obtained, in Guinea and Guyana, by expressing, as also by boiling, the fruit of the *avouira elais*. It has an orange color, a smell of violets, a bland taste, is lighter than water, melts at 84° Fahr., becomes rancid and pale by exposure to air, dissolves in boiling alcohol, and consists of 69 parts of oleine, and 31 of stearine, in 100. It is employed chiefly for making yellow soap. It may be bleached by the action of either chlorine or oxygen gas, as also by that of light and heat.

Palm oil imported in 1850, 447,797 cwts., in 1851, 608,550 cwts.; exported in 1850, 73,186 cwts., in 1851, 114,952 cwts.

PAPER CLOTH. The preparation of this fabric is thus described in the specification of Mr. Henry Chapman's patent of January, 1843. A suitable quantity of canvass, gauze, muslin, calico, linen, &c., is wound upon a roller, which is introduced between the third press felt of a Fourdrinier paper machine; and between the above roller and the endless felt a trough is introduced, containing a solution of gum, glue, &c., with a roller partially immersed in it. Pulp being now allowed to flow upon the endless wire wheel of the machine, paper is made in the ordinary way; and when the endless sheet of paper has been led through the machine, the end of the cloth is brought over the upper part of the roller in the trough, and moved onwards in the direction the paper is proceeding. The motion of the cloth causes the roller to revolve, and the adhesive material carried upon its surface is imparted to the cloth, which is then laid upon the paper, as it passes over the roller immediately preceding the third or last press-roller. By passing between these rollers, the cloth and paper are firmly united, and being dried by the steam cylinders, form the compound fabric. If required, a paper surface may be applied to the other side of the cloth, by repeating the operation. If the cloth be dressed with strong starch, the bath of adhesive solution may be dispensed with. The following prescription is given for making that solution:—

Dissolve in 15 parts of water, 4 of soda, and combine with this solution, by means of heat, 9 parts of yellow rosin; boil for an hour, adding a little linseed oil to prevent frothing, and add 1 part of glue to the mixture; after which dilute the whole with one and a half times its weight of water, and strain through flannel. Thirty parts of this composition are to be mixed with one part of flour-paste, and six parts of paper-pulp, which mixture is to be used warm.

PAPER CUTTING. Mr. T. B. Crompton, of Farnworth, Lancashire, who obtained a patent in May, 1821, for proposing to conduct the newly formed web of paper in the Fourdrinier machine over heated cylinders, for the purpose of drying it expeditiously, in imitation of the mode so long practised in drying calicoes, obtained, along with Enoch Miller, another, in May, 1828, for cutting the endless web of paper lengthwise, by revolving circular blades, fixed upon a roller, parallel to a cylinder, round which the paper is lapped, and progressively unwound.

A patent had been obtained two months before, for certain improvements in cutting

paper, by Mr. Edward Cowper, consisting of a machine, with a reel on which the web of paper of very considerable length has been previously wound, in the act of being made in a Fourdrinier's machine; this web of paper being of sufficient width to produce two, three, or more sheets, when cut.

The several operative parts of the machine are mounted upon standards, or frame-work of any convenient form or dimensions, and consist of travelling endless tapes to conduct the paper over and under a series of guide rollers; of circular rotatory cutters for the purpose of separating the web of paper into strips equal to the widths of the intended sheets; and of a saw-edged knife, which is made to slide horizontally for the purpose of separating the strips into such portions or lengths as shall bring them to the dimensions of a sheet of paper.

The end of the web of paper from the reel *a*, fig 1029 is first conducted up an inclined plane *b* by hand; it is then taken hold of by endless tapes extended upon rollers, as in Mr. Cowper's PRINTING MACHINE, which see. These endless tapes carry the web of paper to the roller *c*, which is pressed against the roller *d* by weighted levers, acting upon the plunger blocks that its axle is mounted in. The second roller *d* may be either of wood or metal, having several grooves formed round its periphery for the purpose of receiving the edges of the circular cutters *e*, (see CARD-CUTTING) mounted upon an axle turning upon bearings in the standards or frame.

In order to allow the web of paper to proceed smoothly between the two rollers, *c*, *d*, a narrow rib of leather is placed round the edges of one or both of these rollers,

for the purpose of leaving a free space between them, through which the paper may pass without wrinkling.

From the first roller *c*, the endless tapes conduct the paper over the second *d*, and then under a pressing roller *f*, in which progress the edges of the circular knives *e*, revolving in the grooves of the second roller *d*, cut the web of paper longitudinally into strips of such widths as may be required, according to the number of the circular cutters and distances between them.

The strips of paper proceed onward from between the knife roller *d* and pressing roller *f*, conducted by tapes, until they reach a fourth roller *g*, when they are allowed to descend, and to pass through the apparatus designed to cut them transversely; that is, into sheet lengths.

The apparatus for cutting the strips into sheets is a sliding knife, placed horizontally upon a frame at *h*, which frame, with the knife *e*, is moved to and fro by a jointed rod *i*, connected to a crank on the axle of the pulley *k*. A flat board or plate *l* is fixed to the standard frame in an upright position, across the entire width of the machine; and this board or

plate has a groove or opening cut along it opposite to the edge of the knife. The paper descending from the fourth roller *g* passes against the face of this board, and as the carriage with the knife advances, two small blocks, mounted upon rods with springs *m m*, come against the paper, and hold it tight to the board or plate *l*, while the edge of the knife is pushed forwards into the groove of that board or plate, and its sharp saw-shaped teeth passing through the paper, cut one row of sheets from the descending strips; which, on the withdrawing of the blocks, falls down, and is collected on the heap below.

The power for actuating this machine is applied to the reverse end of the axle, on which the pulley *k* is fixed, and a band *n, n, n, n*, passing from this pulley over tension wheels *o*, drives the wheel *q* fixed to the axle of the knife roller *d*; hence this roller receives the rotatory motion which causes it to conduct forward the web of paper, but the other rollers *c* and *f*, are impelled solely by the friction of contact.

The rotation of the crank on the axle of *k*, through the intervention of the crank-rod *i*, moves the carriage *h*, with the knife, to and fro at certain periods, and when the spring blocks *m* come against the grooved plate *l*, they slide their guide rods into them, while the knife advances to sever the sheets of paper. But as sheets of different dimensions are occasionally required, the lengths of the slips delivered between each return of the knife are to be regulated by enlarging or diminishing the diameter of the pulley *k*, which will of course retard or facilitate the rotation of the three conducting rollers, *c, d, f*, and cause a greater or less length of the paper to descend between each movement of the knife carriage.

The groove of this pulley *k*, which is susceptible of enlargement, is constructed of wedge-formed blocks passed through its sides, and meeting each other in opposite directions, so that on drawing out the wedges a short distance, the diameter of the pulley becomes diminished; or by pushing the wedges further in, the diameter is increased; and a tension wheel *p* being suspended in a weighted frame, keeps the band always tight.

As it is necessary that the paper should not continue descending while it is held by the blocks *m, m* to be cut, and yet that it should be led on progressively over the knife roller *d*, the fourth roller *g*, which hangs in a lever *j*, is made to rise at that time, so as to take up the length of paper delivered, and to descend again when the paper is withdrawn. This is effected by a rod *r*, connected to the crank on the shaft of the aforesaid roller *k*, and also to the under part of the lever *j*, which lever hanging loosely upon the axle of the knife roller *d*, as its fulcrum, vibrates with the under roller *g*, so as to effect the object in the way described.

The patentee states that several individual parts of this machine are not new, and that some of them are to be found included in the specifications of other persons, such as the circular cutters *e*, which are employed by Mr. Dickinson (CARD-CUTTING), and the horizontal cutter *h*, by Mr. Hansard; he therefore claims only the general arrangement of the parts in the form of a machine for the purpose of cutting paper, as the subject of his invention.

The machine for cutting paper contrived by John Dickinson, Esq. of Nash Mill was patented in January, 1829. The paper is wound upon a cylindrical roller *a*, fig. 1030

mounted upon an axle, supported in an iron frame or standard. From this roller the paper in its breadth is extended over a conducting drum *b*, also mounted upon an axle turning in the frame or standard, and after passing under a small guide roller, it proceeds through a pair of drawing or feeding rollers *c*, which carry it into the cutting machine.

Upon a table *a, d*, firmly fixed to the floor of the building, there is a series of chisel-edged knives *e, e, e*, placed at such distances apart as the dimensions of the cut sheets of paper are intended to be. These knives are made fast to the table, and against them a series of circular cutters *f, f, f*, mounted in a swinging frame *g, g*, are intended to act. The length

of paper being brought along the table over the edges of the knives, up to a stop *n*, the cutters are then swung forwards, and by passing over the paper against the stationary knives, the length of paper becomes cut into three separate sheets.

The frame *g*, *g*, which carries the circular cutters *f*, *f*, hangs upon a very elevated axle, in order that its pendulous swing may move the cutters as nearly in a horizontal line as possible; and it is made to vibrate to and fro by an eccentric, or crank, fixed upon a horizontal rotatory shaft extending over the drum *b*, considerably above it, which may be driven by any convenient machinery.

The workmen draw the paper from between the rollers *c*, and bring it up to the stop *h*, in the intervals between the passing to and fro of the swing-cutters.

The following very ingenious apparatus for cutting the paper web transversely into any desired lengths, was made the subject of a patent by Mr. E. N. Fourdrinier, in June, 1831, and has since been performing its duty well in many establishments.

Fig. 1031 is an elevation, taken upon one side of the machine; and fig. 1032 is a longitudinal section.

a, *a*, *a*, *a*, are four reels, each covered with one continuous sheet of paper; which reels are supported upon bearings in the frame-work *b*, *b*, *b*. *c*, *c*, *c*, is an endless web of felt-cloth passed over the rollers *d*, *d*, *d*, *d*, which is kept in close contact with the under side of the drum *e*, *e*, seen best in fig. 1032.

The several parallel layers of paper to be cut, being passed between the drum *e*, and the endless felt *c*, will be drawn off their respective reels, and fed into the machine, whenever the driving-band is slid from the loose to the fast pulley upon the end of the main shaft *f*. But since the progressive advance of the paper-webs must be arrested during the time of making the cross cut through it, the following apparatus becomes necessary. A disc *g*, which carries the pin or stud of a crank *i*, is made fast to the end of the driving shaft *f*. This pin is set in an adjustable sliding piece, which may be confined by a screw within the bevelled graduated groove, upon the face of the disc *g*, at variable distances from the axle, whereby the eccentricity of the stud *i*, and of course the throw of the crank, may be considerably varied. The crank stud *i*, is connected by its rod *j*, to the swinging curvilinear rack *k*, which takes into the toothed wheel *l*, that turns freely upon the axle of the feed drum *e*, *e*. From that wheel the arms *m*, *m*, rise, and bear one or more palls *n*, which work in the teeth of the great ratchet wheel *o*, *o*, mounted upon the shaft of the drum *e*. The crank-plate *g* being driven round in the direction of its arrow, will communicate a see-saw movement to the toothed arc *k*, next to the toothed wheel *l* in gearing with it, and an oscillatory motion to the arms *m*, *m*, as also to their surmounting pall *n*.

is, whereby the eccentricity of the stud *i*, and of course the throw of the crank, may be considerably varied. The crank stud *i*, is connected by its rod *j*, to the swinging curvilinear rack *k*, which takes into the toothed wheel *l*, that turns freely upon the axle of the feed drum *e*, *e*. From that wheel the arms *m*, *m*, rise, and bear one or more palls *n*, which work in the teeth of the great ratchet wheel *o*, *o*, mounted upon the shaft of the drum *e*.

The crank-plate *g* being driven round in the direction of its arrow, will communicate a see-saw movement to the toothed arc *k*, next to the toothed wheel *l* in gearing with it, and an oscillatory motion to the arms *m*, *m*, as also to their surmounting pall *n*.

In its swing to the left hand, the catch of the pall will slide over the slope of the teeth of the ratchet wheel *o*; but in its return to the right hand, it will lay hold of these teeth and pull them, with their attached drum, round a part of a revolution. The layers of paper in close contact with the under half of the drum will be thus drawn forward at intervals, from the reels, by the friction between its surface and the endless felt, and in lengths corresponding to the arc of vibration of the pall. The knife for cutting these lengths transversely is brought into action at the time when the swing arc is making its inactive stroke, viz., when it is sliding to the left over the slopes of the ratchet teeth *o*. The extent of this vibration varies according to the distance of the crank stud *i*, from the centre *f*, of the plate *g*, because that distance regulates the extent of the oscillations of the curvilinear rack, and that of the rotation of the drum *e*, by which the paper is fed forwards to the knife apparatus. The proper length of its several layers being by the above described mechanism carried forward over the bed *r* of the cutting knife or shears *r*, *v*, whose under blade *r* is fixed, the wiper *s*, in its revolution with the shaft *f*, lifts the tail of the lever *t*, consequently depresses the transverse moveable blade *v* (as shown in fig. 783), and slides the slanting blades across each other obliquely, like a pair of scissors, so as to cause a clean cut across the plies of paper. But just before the shears begin to operate, the transverse board *u* descends to press the paper with its edge, and hold it fast upon the bed *r*. During the action of the upper blade *v*, against the under *r*, the fall board *u*, is suspended by a cord passing across pulleys from the arm *y* of the bell-crank lever *t*, *t*. Whenever the lifter cam *s*, has passed away from the tail of the bell-crank *t*, the weight *z*, hung upon it, will cause the blade *v*, and the pinching board *u*, to be moved up out of the way of the next length of paper, which is regularly brought forward by the rotation of the drum *e*, as above described. The upper blade of the shears is not set parallel to the shaft of the drum, but obliquely to it, and is, moreover, somewhat curved, so as to close its edge progressively upon that of the fixed blade. The blade *v* may also be set between two guide pieces, and have the necessary motion given to it by levers.

PAPER-HANGINGS, called more properly by the French, *papiers peints*. The art of making paper-hangings, *papier de tenture*, has been copied from the Chinese, among whom it has been practised from time immemorial. The English first imported and began to imitate the Chinese paper-hangings; but being exposed till very lately to a high excise duty upon the manufacture, they have not carried it to that extent and pitch of refinement which the French genius has been enabled to do, unchecked by taxation. The first method of making this paper was stencilling; by laying upon it, in an extended state, a piece of pasteboard having spaces cut out of various figured devices, and applying different water colors with the brush. Another piece of pasteboard with other patterns cut out was next applied, when the former figures were dry, and new designs were thus imparted. By a series of such operations, a tolerable pattern was executed, but with no little labor and expense. The processes of the calico printer were next resorted to, in which engraved blocks of the pear or sycamore were employed to impress the colored designs.

Paper-hangings may be distinguished into two classes; 1. those which are really painted, and which are designed in France under the title of *papiers peints*, with brilliant flowers and figures; and 2. those in which the designs are formed by foreign matters applied to the paper, under the name of *papier loutisse*, or flock paper.

The operations common to paper-hangings of both kinds, may be stated as follows:—

1. The paper should be well sized.
2. The edges should be evenly cut by an apparatus like the bookbinder's press.
3. The ends of each of the 24 sheets which form a piece, should be nicely pasted together; or a Foudrinier web of paper should be taken.
4. Laying the grounds, is done with earthy colors or colored lakes thickened with size, and applied with brushes.

An expert workman, with one or two children, can lay the grounds of 300 pieces in a day. The pieces are now suspended upon poles near the ceiling, in order to be dried. They are then rolled up and carried to the apartment where they are polished, by being laid upon a smooth table, with the painted side undermost, and rubbed with the polisher. Pieces intended to be satined, are grounded with fine Paris plaster, instead of Spanish white; and are not smoothed with a brass polisher, but with a hard brush attached to the lower end of the swing polishing rod. After spreading the piece upon the table with the grounded side undermost, the paper-stainer dusts the upper surface with finely powdered chalk of Briançon, commonly called talc, and rubs it strongly with the brush. In this way the satiny lustre is produced.

THE PRINTING OPERATIONS.

Blocks about two inches thick, formed of three separate boards glued together, of which two are made of poplar, and one (that which is engraved) of pear-tree or syc

more, are used for printing paper-hangings, as for calicoes. The grain of the upper layer of wood should be laid across that of the layer below. As many blocks are required as there are colors and shades of color. To make the figure of a rose, for example, three several reds must be applied in succession, the one deeper than the other, a white for the clear spaces, two and sometimes three greens for the leaves, and two wood colors for the stems; altogether from 9 to 12 for a rose. Each block carries small pin points fixed at its corners to guide the workman in the insertion of the figure exactly in its place. An expert hand places these guide pins so that their marks are covered and concealed by the impression of the next block; and the finished piece shows merely those belonging to the first and last blocks.

In printing, the workman employs the same *swimming-tub* apparatus which has been described under block printing (see CALICO-PRINTING), takes off the color upon his blocks, and impresses them on the paper extended upon a table in the very same way. The tub in which the drum or frame covered with calf-skin is inverted, contains simply water thickened with parings of paper from the bookbinder, instead of the pasty mixture employed by the calico-printers. In impressing the color by the block upon the paper, he employs a lever of the second kind, to increase the power of his arm, making it act upon the block through the intervention of a piece of wood, shaped like the bridge of a violin. This tool is called *tasseau* by the French. A child is constantly occupied in spreading color with a brush upon the calf-skin head of the drum or sieve, and in sliding off the paper upon a wooden trestle or horse, in proportion as it is finished. When the piece has received one set of colored impressions, the workman, assisted by his little aid, called a *tireur* (drawer), hooks it upon the drying-poles under the ceiling. A sufficient number of pieces should be provided to keep the printer occupied during the whole at least of one day, so that they will be dried and ready to receive another set of colored impressions by the following morning.

All the colors are applied in the same manner, every shade being formed by means of the blocks, which determine all the beauty and regularity of the design. A pattern drawer of taste may produce a very beautiful effect. The history of Psyche and Cupid, by M. Dufour, has been considered a masterpiece in this art, rivaling the productions of the pencil in the gradation, softness, and brilliancy of the tints.

When the piece is completely printed, the workman looks it all over, and if there be any defects, he corrects them by the brush or pencil, applying first the correction of one color, and afterwards of the rest.

A final satining, after the colors are dried, is communicated by the friction of a finely polished brass roller, attached by its end gudgeons to the lower extremity of a long swing-frame; and acting along the cylindrical surface of a smooth table, upon which the paper is spread.

The *fondou* or rainbow style of paper-hangings, which I have referred to this place in the article CALICO-PRINTING, is produced by means of an assortment of oblong narrow tin pans, fixed in a frame, close side to side, each being about one inch wide, two inches deep, and eight inches long; the colors of the prismatic spectrum, red, orange, yellow, green, &c., are put, in a liquid state, successively in these pans; so that when the oblong brush *a, b*, with guide ledges *c, d*, is dipped into them across the whole of the

parallel row at once, it comes out impressed with the different colors at successive points *e, e, e, e*, of its length, and is then drawn by the paper-stainer over the face of the woollen drum head, or sieve of the swimming tub, upon which it leaves a corresponding series of stripes in colors, graduating into one another like those of the prismatic spectrum. By applying his block to the *tear*, the workman takes up the color in rainbow hues, and transfers these to the paper. *f, f, f, f* show the separate brushes in tin sheaths, set in one frame.

At M. Zuber's magnificent establishment in the ancient château of Rixheim, near Mulhouse, where the most beautiful French *papiers peints* are produced, and where I was informed that no less than 3000 blocks are required for one pattern, I saw a two-color calico machine employed with great advantage, both as to taste and expedition. Steam-charged cylinders were used to dry the paper immediately after it was printed, as the colors, not being so rapidly absorbed as they are by calico, would be very apt to spread.

The operations employed for common paper-hangings, are also used for making flock paper, only a stronger size is necessary for the ground. The flocks are obtained from the woollen cloth manufacturers, being cut off by their shearing machines, called *lèwises* by the English workmen, and are preferred in a white state by the French paper-hanging makers, who scour them well, and dye them of the proper colors themselves. When they are thoroughly stove-dried, they are put into a conical fluted mill, like that for making snuff, and are properly ground. The powder thus obtained is afterwards sifted by a bolting-machine, like that of the flour mill, whereby flocks of different degrees of fineness are produced. These are applied to the paper after it has undergone all the

usual printing operations. Upon the workman's left hand, and in a line with his printing table, a large chest is placed for receiving the flock powders: it is seven or eight feet long, two feet wide at the bottom, three feet and a half at top, and from 15 to 18 inches deep. It has a hinged lid. Its bottom is made of tense calf-skin. This chest is called the *drum*; it rests upon four strong feet, so as to stand from 24 to 28 inches above the floor.

The block which serves to apply the adhesive basis of the velvet-powders, bears in relief only the pattern corresponding to that basis, which is formed with linseed oil, rendered drying by being boiled with litharge, and afterwards ground up with white lead. The French workmen call this mordant the *encaustic*. It is put upon the cloth which covers the inverted swimming tub, in the same way as the common colors are, and is spread with a brush by the *tireur* (corruptly styled *tearer* by some English writers). The workman daubs the blocks upon the mordant, spreads the pigment even with a kind of brush, and then applies it by impression to the paper. Whenever a sufficient surface of the paper has been thus covered, the child draws it along into the great chest, sprinkling the flock powder over it with his hands; and when a length of 7 feet is printed, he covers it up within the drum, and beats upon the calf-skin bottom with a couple of rods to raise a cloud of flock inside, and to make it cover the prepared portion of the paper uniformly. He now lifts the lid of the chest, inverts the paper, and beats its back lightly, in order to detach all the loose particles of the woolly powder.

By the operation just described, the velvet-down being applied everywhere of the same color, would not be agreeable to the eye, if shades could not be introduced to relieve the pattern. To give the effect of drapery, for example, the appearance of folds must be introduced. For this purpose, when the piece is perfectly dry, the workman stretches it upon his table, and by the guidance of the pins in his blocks, he applies to the flock surface a color in distemper, of a deep tint, suited to the intended shades, so that he dyes the wool in its place. Light shades are produced by applying some of his lighter water-colors.

Gold leaf is applied upon the above mordant, when nearly dry; which then forms a proper gold size; and the same method of application is resorted to, as for the ordinary gilding of wood. When the size has become perfectly hard, the superfluous gold leaf is brushed off with a dossil of cotton wool or fine linen.

The colors used by the paper-hangers are the following:—

1. *Whites*. These are either white-lead, good whitening, or a mixture of the two.
2. *Yellows*. These are frequently vegetable extracts; as those of weld, or of Avignon or Persian berries, and are made by boiling the substances with water. Chrome yellow is also frequently used, as well as the *terra di Sienna* and yellow ochre.
3. *Reds* are almost exclusively decoctions of Brazil wood.
4. *Blues* are either Prussian blue, or blue verditer.
5. *Greens* are Scheele's green, a combination of arsenious acid, and oxyde of copper; the green of Schweinfurth, or green verditer; as also a mixture of blues and yellows.
6. *Violets* are produced by a mixture of blue and red in various proportions, or they may be obtained directly by mixing a decoction of logwood with alum.
7. *Browns, blacks, and grays*. Umber furnishes the brown tints. Blacks are either common ivory or Frankfort black; and grays are formed by mixtures of Prussian blue and Spanish white.

All the colors are rendered adhesive and consistent, by being worked up with gelatinous size or a weak solution of glue, liquefied in a kettle. Many of the colors are previously thickened, however, with starch. Sometimes colored lakes are employed. See *LAKES*.

PAPER, MANUFACTURE OF. (*Papeterie*, Fr.; *Papiermacherkunst*, Germ.) This most useful substance, which has procured for the moderns an incalculable advantage over the ancients, in the means of diffusing and perpetuating knowledge, seems to have been first invented in China, about the commencement of the Christian era, and was thence brought to Mecca, along with the article itself, about the beginning of the 8th century; whence the Arabs carried it, in their rapid career of conquest and colonization, to the coasts of Barbary, and into Spain, about the end of the 9th or beginning of the 10th century.

By other accounts, this art originated in Greece, where it was first made from cotton fibres, in the course of the tenth century, and continued there in common use during the next three hundred years. It was not till the beginning of the 14th century that paper was made from linen in Europe, by the establishment of a paper-mill in 1390, at Nuremberg in Germany. The first English paper-mill was erected at Dartford by a German jeweller in the service of Queen Elizabeth, about the year 1588. But the business was not very successful; in consequence of which, for a long period afterwards, indeed till within the last 70 years, this country derived its supplies of fine writing papers from France and Holland. Nothing places in a more striking light the

vast improvement which has taken place in all the mechanical arts of England since the era of Arkwright, than the condition of our paper-machine factories now, compared with those on the Continent. Almost every good automatic paper mechanism at present mounted in France, Germany, Belgium, Italy, Russia, Sweden, and the United States, has either been made in Great Britain, and exported to these countries, or has been constructed in them closely upon the English models.

Till within the last 30 years, the linen and hempen rags from which paper was made, were reduced to the pasty state of comminution requisite for this manufacture by mashing them with water, and setting the mixture to ferment for many days in close vessels, whereby they underwent in reality a species of putrefaction. It is easy to see that the organic structure of the fibres would be thus unnecessarily altered, nay, frequently destroyed. The next method employed, was to beat the rags into a pulp by stamping rods, shod with iron, working in strong oak mortars, and moved by water-wheel machinery. So rude and ineffective was the apparatus, that forty pairs of stamps were required to operate a night and a day, in preparing one hundred weight of rags. The pulp or paste was then diffused through water, and made into paper by methods similar to those still practised in the small hand-mills.

About the middle of the last century, the cylinder or engine mode, as it is called, of comminuting rags into paper pulp, was invented in Holland; which was soon afterwards adopted in France, and at a later period in England.

The first step in the paper manufacture, is the sorting of the rags into four or five qualities. They are imported into this country chiefly from Germany, and the ports of the Mediterranean. At the mill they are sorted again more carefully, and cut into shreds by women. For this purpose a table frame is covered at top with wire cloth, containing about nine meshes to the square inch. To this frame a long steel blade is attached in a slanting position, against whose sharp edge the rags are cut into squares or fillets, after having their dust thoroughly shaken out through the wire cloth. Each piece of rag is thrown into a certain compartment of a box, according to its fineness; seven or eight sorts being distinguished. An active woman can cut and sort nearly one cwt. in a day.

The sorted rags are next dusted in a revolving cylinder surrounded with wire cloth, about six feet long, and four feet in diameter, having spokes about 20 inches long, attached at right angles to its axis. These prevent the rags from being carried round with the case, and beat them during its rotation; so that in half an hour, being pretty clean, they are taken out by the side door of the cylinder, and transferred to the engine, to be first washed, and next reduced into a pulp. For fine paper, they should be previously boiled for some time in a caustic ley, to cleanse and separate their filaments.

The construction of the *stuff-engine* is represented in *figs. 1035 1036*. *Fig. 1035* is the longitudinal section, and *fig. 1036* the plan of the engine.

The large vat is an oblong cistern rounded at the angles. It is divided by the partition *b, b*, and the whole inside is lined with lead. The cylinder *c*, is made fast to the spindle *d*, which extends across the engine, and is put in motion by the pinion *p*, fixed to its extremity. The cylinder is made of wood, and furnished with a number of blades or cutters, secured to its circumference, parallel to the axis, and projecting about an inch above its surface. Immediately beneath the cylinder a block of wood *k* is placed. This is mounted with cutters like those of the cylinder, which in their

revolution pass very near to the teeth of the block, but must not touch it. The distance between these fixed and moving blades is capable of adjustment by elevating or depressing the bearings upon which the necks *e, e*, of the shaft are supported. These bearings rest upon two levers *g, g*, which have tenons at their ends, fitted into upright mortises, made in short beams *h, h*, bolted to the sides of the engine. The one end of

the levers *g, g*, is moveable, while the other end is adapted to rise and fall upon bolts in the beams *h, h*, as centres. The front lever, or that nearest to the cylinder *c*, is capable of being elevated or depressed, by turning the handle of a screw (not seen in this view), which acts in a nut fixed to the tenon of *g*, and comes up through the top of the beam *h*, upon which the head of the screw takes its bearing. Two brasses are let into the middle of the levers *g, g*, and form the bearings for the shaft of the engine to turn upon. The above-mentioned vertical screw is used to raise or lower the cylinder, and cause it to cut coarser or finer, by enlarging or diminishing the space between the fixed cutters in the block and those in the cylinder.

To the left hand of *i*, fig. 1035 is a circular breasting made of boards, and covered with sheet lead; it is curved to fit the cylinder very truly, and leaves but very little space between the teeth and breasting; at its bottom, the block *k* is fixed. The engine is supplied with water from a pump, by a pipe, which delivers it into a small cistern, near to and communicating with the engine. A stopcock cuts off or regulates the supply of water at pleasure, and a grating covered with hair-cloth is fixed across that small cistern, to intercept any filth that may be floating in the water; in other cases a flannel bag is tied round the nose of the stopcock, to act as a filter.

The rags being put into the engine filled with water, are drawn by the rapid rotation of the cylinder between the two sets of cutters, whereby they are torn into the finest filaments, and by the impulsion of the cylinder they are floated over the top of the breasting upon the inclined plane. In a short time more rags and water are raised into that part of the engine vat. The tendency in the liquid to maintain an equilibrium, puts the whole contents of the cistern in slow motion down the inclined plane, to the left hand of *i*, and round the partition *b, b*, (see the arrow), whereby the rags come to the cylinder again in the space of about 20 minutes; so that they are repeatedly drawn out and separated in all directions till they are reduced to the appearance of a pulp.

This circulation is particularly useful, by turning over the rags in the engine, causing them to be presented to the cutter at different angles every time; otherwise, as the blades always act in one direction, the comminution would not be so complete. The cutting is performed as follows: The teeth of the block are set somewhat obliquely to the axes of the cylinder, as shown by fig. 1037 but the teeth of the cylinder *c* itself are set

1037

parallel to its axis; therefore the cutting edges meet at a small angle, and come in contact, first at the one end, and then towards the other, by successive degrees, so that any rags coming between them, are torn as if between the blades of a pair of forceps. Sometimes the blades *k* in the block are bent to an angle in the middle, instead of being straight and inclined to the cylinder. These are called elbow plates; their

two ends being inclined in opposite directions to the axis of the cylinder. In either case, the edges of the plates of the block cannot be straight lines, but must be curved, to adapt themselves to the curve which a line traced on the cylinder will necessarily have. The plates or blades are united by screwing them together, and fitting them into a cavity cut into the wooden block *k*. Their edges are bevelled away upon one side only.

The block is fixed in its place by being made dovetailed, and truly fitted into the bottom of the cistern, so that the water will not leak through its junction. The end of it comes through the woodwork of the chest, and projects to a small distance on its outside, being kept in its place by a wedge. By withdrawing this wedge, the block becomes loose, and can be removed in order to sharpen the cutters, as occasion may be. This is done at a grindstone, after detaching the plates from each other.

The cutters of the cylinder are fixed into grooves, cut in the wood of the cylinder, at equal distances asunder, round its periphery, in a direction parallel to its axis. The number of these grooves is twenty, in the machine here represented. For the *washer*, each groove has two cutters put into it; then a fillet of wood is driven fast in between them, to hold them firm; and the fillets are secured by spikes driven into the solid wood of the cylinder. The *beater* is made in the same manner, except that each groove contains three bars and two fillets.

In the operation of the cylinder, it is necessary that it should be enclosed in a case, or it would throw all the water and rags out of the engine, in consequence of its great velocity. This case is a wooden box *m, m*, fig. 1035 enclosed on every side except the bottom; one side of it rests upon the edge of the vat, and the other upon the edge of the partition *b, b*, fig. 1036. The diagonal lines *m, r*, represent the edges of wooden frames, which are covered with hair or wire-cloth, and immediately behind these the box is furnished with a bottom and a ledge towards the cylinder, so as to form a complete trough. The square figures under *n, n*, in fig. 1035 show the situation of two openings or spouts through the side of the case, which conduct to flat lead-pipes, one of which is seen near the upper *g* in fig. 1036 placed by the side of the vat; the beam being cut away from them. These are waste pipes to discharge the foul water from the engine; because the

cylinder, as it turns, throws a great quantity of water and rags up against the sieves, the water goes through them, and runs down to the trough under *n, n*, and thence into the ends of the flat leaden pipes, through which it is discharged. *o, o*, fig. 1055 are grooves for two boards, which, when put down in their places, cover the hair sieves, and stop the water from going through them, should it be required in the engine. This is always the case in the beating engines, and therefore they are seldom provided with these waste pipes, or at most on one side only; the other side of the cover being curved to conform to the cylinder. Except this, the only difference between the washing engine and the beater, is that the teeth of the latter are finer, there being 60 instead of 40 blades in the periphery; and it revolves quicker than the washer, so that it will tear out and comminute those particles which pass through the teeth of the washer. In small mills, when the supply of water is limited, there is frequently but one engine, which may be used both for washing and beating, by adjusting the screw so as to let the cylinder down and make its teeth work finer. But the system in all considerable works, is to have two engines at least, or four if the supply of water be great. The power required for a 5 or 6 vat mill, is about 20 horses in a water-wheel or steam engine.

In the above figures only one engine is shown, namely, the *finisher*; there is another, quite similar, placed at its end, but on a level with its surface, which is called the *washer*, in which the rags are first worked coarsely with a stream of water, running through them to wash and open their fibres; after this washing they are called *half-stuff*, and are then let down into the bleaching engine, and next into the *beating* engine, above described.

By the arrangements of the mill gearing, the two cylinders of the *washer* and *beater* engines make from 120 to 150 revolutions per minute, when the water-wheel moves with due velocity. The beating engine is always made to move, however, much faster than the washing one, and nearly in the ratio of the above numbers.

The vibratory noise of a washing engine is very great; for when it revolves 120 times per minute, and has 40 teeth, each of which passes by 12 or 14 teeth in the block at every revolution, it will make nearly 60,000 cuts in a minute, each of them sufficiently loud to produce a most grating growling sound. As the beater revolves quicker, having perhaps 60 teeth, instead of 40, and 20 or 24 cutters in the block, it will make 180,000 cuts in a minute. This astonishing rapidity produces a coarse musical humming, which may be heard at a great distance from the mill. From this statement, we may easily understand how a modern engine is able to turn out a vastly greater quantity of paper pulp in a day than an old mortar machine.

The operation of grinding the rags requires nice management. When first put into the washing engine they should be worked gently, so as not to be cut, but only powerfully scrubbed, in order to enable the water to carry off the impurities. This effect is obtained by raising the cylinder upon its shaft, so that its teeth are separated considerably from those of the block. When the rags are comminuted too much in the washer, they would be apt to be carried off in part with the stream, and be lost; for at this time the water-cock is fully open. After washing in this way for 20 or 30 minutes, the bearings of the cylinder are lowered, so that its weight rests upon the cutters. Now the supply of water is reduced, and the rags begin to be torn, at first with considerable agitation of the mass, and stress upon the machinery. In about three or four hours, the engine comes to work very smoothly, because it has by this time reduced the rags to the state of *half-stuff*. They are then discharged into a large basket, through which the water drains away.

The bleaching is usually performed upon the *half-stuff*. At the celebrated manufactory of Messrs. Montgolfier, at Annonay, near Lyons, chlorine gas is employed for this purpose with the best effect upon the paper, since no lime or muriate of lime can be thus left in it; a circumstance which often happens to English paper, bleached in the washing engine by the introduction of chloride of lime among the rags, after they have been well washed for three or four hours by the rotation of the engine. The current of water is stopped whenever the chloride of lime is put in. From 1 to 2 pounds of that chemical compound are sufficient to bleach 1 cwt. of fine rags, but more must be employed for the coarser and darker colored. During the bleaching operation the two sliders *o, o*, fig. 1035 are put down in the cover of the cylinder, to prevent the water getting away. The engine must be worked an hour longer with the chloride of lime, to promote its uniform operation upon the rags. The cylinder is usually raised a little during this period, as its only purpose is to agitate the mass, but not to triturate it. The water-cock is then opened, the boards *m, m* are removed, and the washing is continued for about an hour, to wash the salt away; a precaution which ought to be better attended to than it always is by paper manufacturers.

The *half-stuff* thus bleached is now transferred to the beating engine, and worked into fine pulp. This operation takes from 4 to 5 hours, a little water being admitted from time to time, but no current being allowed to pass through, as in the washing engine

The softest and fairest water should be selected for this purpose; and it should be administered in nicely regulated quantities, so as to produce a proper spissitude of stuff for making paper.

For printing paper, the *sizing* is given in the beating engine, towards the end of its operation. The size is formed of alum in fine powder, ground up with oil; of which mixture about a pint and a half are thrown into the engine at intervals, during the last half-hour's beating. Sometimes a little indigo blue or smalt is also added, when a peculiar bloom color is desired. The pulp is now run off into the stuff chest, where the different kinds are mixed; whence it is taken out as wanted. The chest is usually a rectangular vessel of stone or wood lined with lead, capable of containing 300 cubic feet at least, or 3 engines full of stuff. Many paper-makers prefer round chests, as they admit of rotatory agitators.

When the paper is made in single sheets, by hand labor, as in the older establishments, a small quantity of the stuff is transferred to the working-vat by means of a pipe, and there diluted properly with water. This vat is a vessel of stone or wood, about 5 feet square, and 4 deep, with sides somewhat slanting. Along the top of the vat a board is laid, with copper fillets fastened lengthwise upon it, to make the mould slide more easily along. This board is called the bridge. The maker stands on one side; and has to his left hand a smaller board, one end of which is made fast to the bridge, while the other rests on the side of the vat. In the bridge opposite to this, a nearly upright piece of wood, called the ass, is fastened. In the vat there is a copper, which communicates with a steam pipe to keep it hot; there is also an agitator, to maintain the stuff in a uniform consistence.

The moulds consist of frames of wood, neatly joined at the corners, with wooden bars running across, about an inch and a half apart. Across these, in the length of the moulds, the wires run, from fifteen to twenty per inch. A strong raised wire is laid along each of the cross bars, to which the other wires are fastened; this gives the laid paper its ribbed appearance.

The water-mark is made by sewing a raised piece of wire in the form of letters, or any figured device, upon the wires of the mould, which makes the paper thinner in these places. The frame-work of a *wove* mould is nearly the same; but instead of sewing on separate wires, the frame is covered with fine wire cloth, containing from 48 to 64 meshes per inch square. Upon both moulds a *deckel*, or moveable raised edge-frame, is used; which must fit very neatly, otherwise the edges of the paper will be rough.

A pair of moulds being laid upon the bridge, the workman puts on the *deckel*, brings the mould into a vertical position, dips it about half way down into the stuff before him, then turning it into a horizontal position, covers the mould with the stuff and shakes it gently. This is a very delicate operation; for if the mould be not held perfectly level, one part of the sheet will be thicker than another. The sheet thus formed has, however, no coherence; so that by turning the mould, and dipping the wire cloth surface in the vat, it is again reduced to pulp if necessary. He now pushes the mould along the small board to the left, and removes the *deckel*. Here another workman called the *coucher* receives it, and places it at rest upon the ass, to drain off some of the water. Meanwhile the *vat-man* puts the *deckel* upon the other mould, and makes another sheet. The *coucher* stands to the left side of the vat, with his face towards the *vat-man* or maker, on his right is the press furnished with felt cloths, or porous flannels; a three-inch thick plank lies before him on the ground. On this he lays a cushion of felts, and on this another felt; he then turns the paper wire mould, and presses it upon the felt, where the sheet remains. He now returns the mould by pushing it along the bridge. The maker has by this time another sheet ready for the *coucher*; which, like the preceding, is laid upon the ass, and then couched or inverted upon another felt, laid down for the purpose.

In this way, felts and paper are alternately stratified, till a heap of six or eight quires is formed, which is from 15 to 18 inches high. This mass is drawn into the press, and exposed to a force of 100 tons or upwards. After it is sufficiently compressed, the machine is relaxed, and the elasticity of the flannel makes the rammer descend (if a hydraulic press be used) with considerable rapidity. The felts are then drawn out on the other side by an operative called a *layer*, who places each felt in succession upon one board, and each sheet of paper upon another. The *coucher* takes immediate possession of the felts for his further operations.

Two men at a vat, and a boy as a layer or lifter, can make about 6 or 8 reams in 10 hours. In the evening the whole paper made during the day is put into another press, and subjected to moderate compression, in order to get quit of the mark of the felt, and more of the water. Next day it is all separated, a process called parting, and being again pressed, is carried into the loft. Fine papers are often twice parted and pressed, in order to give them a proper surface.

The next operation is the drying, which is performed in the following way. Posts

about 10 or 12 feet high are erected at the distance of ten feet from each other, and pierced with holes six inches apart; two spars with ropes stretched between them, at the distance of 5 inches from one another, called a treble or tribble, are placed about 5 feet high between these posts, supported by pins pushed into the holes in the posts. The workman takes up 4 or 8 sheets of paper, and puts them upon a piece of wood in the form of a T; passing this T between the ropes, he shifts the sheets upon them, and proceeds thus till all the ropes are full. He then raises the treble, and puts another in its place, which he fills and raises in like manner. Nine or ten trebles are placed in every set of posts. The sides of the drying-room have proper shutters, which can be opened to any angle at pleasure.

When the paper is dry, it is taken down, and laid neatly in heaps to be sized. Size is made of pieces of skin, cut off by the curriers before tanning, or sheep's feet, or any other matter containing much gelatine. These substances are boiled in a copper to a jelly; to which, when strained, a small quantity of alum is added. The workman then takes about 4 quires of paper, spreads them out in the size properly diluted with water, taking care that they be equally moistened. This is rather a nice operation. The superfluous size is then pressed out, and the paper is parted into sheets. After being once more pressed, it is transferred to the drying-room, but must not be dried too quickly. Three days are required for this purpose. When the paper is thoroughly dry, it is carried to the finishing-house, and is again pressed pretty hard. It is then picked by women with small knives, in order to take out the knots, and separate the perfect from the imperfect sheets. It is again pressed, given to the finisher, to be counted into reams, and done up. These reams are compressed, tied up, and sent to the warehouse for sale. A good finisher can count 200 reams, or 96,000 sheets in a day.

Hot pressing is executed by placing a sheet of paper between two smoothed pasteboards, alternately, and between every 50 pasteboards a heated plate of iron, and subjecting the pile to the press. This communicates a fine smooth surface to writing-paper.

The grain of the paper is often disfigured by the felts, when they are too much used, or when the loose fibres do not cover the twisted thread. The two sides of the felt are differently raised, and that on which the fibres are longest is applied to the sheets which are laid down. As the felts have to resist the reiterated action of the press, their warp should be made stout, of long combed wool, and well twisted. The woof, however, should be of carded wool, and spun into a soft thread, so as to render the fabric spongy, and capable of imbibing much water.

This oporose and delicate process of moulding the sheets of paper by hand, has for nearly thirty years past been performed, in many manufactories, by a machine which produces it in a continuous sheet of indefinite length which is afterwards cut into suitable sizes, by the PAPER-CUTTING MACHINE.

In 1799, Louis Robert, then employed in the paper works of Essonne in France, contrived a machine to make paper of a great size, by a continuous motion, and obtained for it a patent for 15 years, with a sum of 8000 francs from the French government, as a reward for his ingenuity. The specification of this patent is published in the second volume of *Brevets d'Invention expirés*. M. Leger-Didot, then director of the said works, bought Robert's machine and patent for 25,000 francs, to be paid by instalments. Having become proprietor of this machine, which, though imperfect, contained the germ of a valuable improvement in paper-making, M. Didot came over with it to England, where he entered into several contracts for constructing and working it.

Meanwhile M. L. Didot having failed to fulfil his obligations to Robert, the latter instituted a law-suit, and recovered possession of his patent by a decision dated 23d June, 1810. Didot then sent over to Paris the Repertory of Arts, for Sept. 1808, which contained the specification of the English patent, with instructions to a friend to secure the improved machines described in it, by a French patent. The patent was obtained, but became inoperative in consequence of M. L. Didot failing to return to France, as he had promised, so as to mount the patent machine within the two years required by the French patent law. It was not till 1815, that M. Calla, machine-maker at Paris, constructed the paper apparatus known in England by the name of Fourdrinier's, and which, on the authority of the *Dictionnaire Technologique*, was very imperfect in comparison of an English made machine imported about that time into France. *La construction de ces machines, qui n'offre pourtant rien de difficile, est restée jusqu'à ce jour exclusivement dans les mains des Anglais*, is the painful acknowledgment made in 1829, for his countrymen, by the author of the elaborate article *Papeterie* in that national work. If there be nothing difficult in the construction of these machines, the French mechanicians ought to be ashamed of forcing their countrymen to seek the sole supply of them in England; for the principal paper works in France, as those of MM. Canson, Montgolfier, Thomas Varenne, Firmin Didot, Delembre, De Maupéon, &c., are mounted with English-made machines.

The following, for example, are a few of the paper-mills in France which are mounted with the self-acting machines of Messrs. Bryan Donkin & Co.

Messrs. Canson, at Annonay.

M. de la Place, at Jean d'Heures, Bar-le-duc.

Société anonyme, at Sainte Marie, under M. Delatouche

Echarcon près Mennecey, (Seine et Oise).

Firmin Didot, Mesnil sur l'Estrée.

M. F. M. Montgolfier, à Annonay.

Muller, Bouchard, Ondin and Co's., at Gueures, near Dieppe.

MM. Richard et Comp. à Plainfoing.

M. Callot-Bellisle; Vieuze et Chantoiseau.

M. Bechétaille, near St. Etienne, at Bourg Argental.

It deserves particularly to be remarked, to the honor of English mechanism, that the proprietors of the first five of the above works received gold medals at the last exposition of their papers at the Louvre, and all the rest received medals either of silver or bronze.*

The following is a true narrative of the rise and progress of the paper automaton.

M. Leger Didot, accompanied by Mr. John Gamble, an Englishman who had resided for several years in Paris, obtained permission from the French government, in 1800, to carry over the small working model of Robert's continuous machine, with the view of getting the benefit of English capital and mechanical skill to bring it into an operative state upon the great scale. Fortunately for the vigorous development of this embryo project, which had proved an abortion in France, they addressed themselves, on the one hand, to a mercantile firm equally opulent and public spirited, and on the other, to engineers distinguished for persevering energy and mechanical resource. A first patent was granted to Mr. Gamble on the 20th of April, 1801, and a second, for certain improvements upon the former, on the 7th of June, 1803. In January, 1804, Mr. Gamble, for certain considerations, assigned these two patents to Messrs. Henry and Sealy Fourdrinier, the house above alluded to, who were at that period, and for several years afterwards, the most considerable stationers and paper-makers in Great Britain. By an act of parliament passed on the 4th of August, 1807, Mr. Gamble's privilege of 14 years from April, 1801, was prolonged to 15 years after the date of the act, being an extension of about 7 years upon the original patent.

The proprietors showed good reasons, in the enormous expense of their experiments, and the national importance of the object, why the patent should have been extended 14 years from the latter date, and would have obtained justice from parliament in this respect, but for an unworthy artifice of Lord Lauderdale in the House of Lords. "He, and he only, was the person who took the objection," and, by introducing a regulation in a standing order of the House of Lords, that none but the original inventor should have an extension, though Mr. H. Fourdrinier was the inventor substantially of the operative machine, he defeated the honorable intentions of his brother peers, whose committee said, "We will give seven years, and Mr. Fourdrinier may apply again, if it should turn out that the seven years that we propose to give to Mr. Fourdrinier should not give sufficient time to afford any chance of his receiving any remuneration for the expense that he has incurred in introducing this invention." The bill passed in the House of Commons for 14 years, but it was limited by this *ruse* of Lord Lauderdale to 7, "who put the standing order upon the books (of the upper house) which prevented Messrs. Fourdrinier from having any benefit from the invention.†

In February, 1808, Mr. Gamble, after losing both his time and money savings during eight years of irksome diligence, assigned over to Messrs. Fourdrinier the whole right of his share in the patent to which he was entitled under the act of parliament.

Dartford in Kent, which had been long conspicuous as the seat of a good manufactory of paper and paper moulds, was selected by the proprietors of the patent as the fittest place for realizing their plans; and happily for them it possessed, in Mr. Hall's engineering establishment, every tool requisite for constructing the novel automaton, and in his assistant, Mr. Bryan Donkin, a young and zealous mechanist, who, combining precision of workmanship with fertility of invention, could turn his local advantages to the best account. To this gentleman, aided by the generous confidence of Messrs. Fourdrinier, the glory of rearing to a stately manhood the helpless bantling of M. L. Didot is entirely due. In 1803, after nearly three years of intense application, he produced a self-acting machine for making an endless web of paper, which was erected at St. Neot's under the superintendence of Mr. Gamble, and performed in such a manner as to surprise every beholder.

Since that important era Mr. Donkin has steadily devoted his whole mind and means

* Rapport de Jury Central, par M. Le Baron Charles Dupin, vol. ii. p. 278; Paris, 1856.

† See this shabby piece of diplomacy unveiled in the Minutes of Evidence taken before the Select Committee of the House of Commons on Fourdrinier's patent; May, 1837.

to the progressive improvement of this admirable apparatus; and has, by the untiring regularity, precision, promptitude, and productiveness of its work, earned for himself a place along with Watt, Wedgewood, and Arkwright, in the temple of mechanical fame.

"*La France*," says a late official eulogist of her arts, and interpreter of her sentiments, "ne craint plus la rivalité des autres peuples pour la fabrication des divers genres de papiers et de cartons."* After this boast, one would not expect to hear him immediately confess that in 1823 his country possessed only one manufactory of the *papier continu*, containing one of the Fourdrinier machines made at London by Mr. Donkin, for M. Canson, at Vidalon-les-Annonay; that in 1827 there were only 4 of these machines in France, and that in 1834 there were not many more than a dozen. He justly observes, that "this mode, being more economical, more rapid, and more powerful, will become henceforth the only one which can be practised without loss. Then will disappear the ancient system of hand-work, which likewise involved the inconveniences, we may say dangers, resulting from combinations among the operatives. The machine-made papers possess many advantages: they can receive, so to speak, unlimited dimensions; they preserve a perfectly uniform thickness throughout all their length; they may be fabricated in every season of the year; nor do they require to be sorted, trimmed, and hung up in the drying-house, operations which occasioned great waste, amounting to no less than one defective sheet out of every five. The continuous paper at one time retained the impression of the wire-wove web on its under side; a defect from which it has been freed by a pressure apparatus of Mr. Donkin, recently imported from England by M. Delatouche."

It appears from documents presented to a committee of the House of Lords in 1807, that the Messrs. Fourdrinier had, by that time, withdrawn from their stationary business the large sum of 60,000*l.*, to further the object of their patent; so many difficulties did they encounter in bringing the machinery to its then comparatively complete state, and so little encouragement or support did they receive from the paper manufacturers throughout the kingdom.

The patentees laid a statement before the public in 1806, containing the following comparative estimate of the expense attending seven vats, and that attending a machine employed upon paper sized in the engine, performing the same quantity of work as seven vats, at the rate of 12 hours daily.

A MACHINE.

In the same statement, it was shown that the expense of making paper by hand is 16s. per cwt., whereas by their machine it is only 3s. 9d.; so that upon 432,000 cwt. the quantity annually made in Great Britain and Ireland (as founded upon the fact that one vat can make 480 cwt. of paper, and that there were 900 vats in the kingdom), the annual saving by the machine would be 264,600l., or 345,600l. — 81,000l.

In a second statement laid before the public in 1807, the patentees observe that their recently improved machine, from its greater simplicity, may be erected at a considerably reduced expense. "Mr. Donkin, the engineer, will engage to furnish machines of the dimensions specified below, with all the present improvements, at the prices specified below.

	Inches.	If driven by straps.	£
3 or 4 vats - - - -	30	between the deckles	715

"Instead of 5 men, formerly employed upon 1 machine, 3 are now (in 1813) fully sufficient, without requiring that degree of attention and skill which was formerly indispensable.

"In 1806 the machine was capable of doing the work of 6 vats in twelve hours; it is, however, now capable of doing double that quantity, at one fourth of the expense. For by the various improvements enumerated above, the consumption of wire is reduced nearly one half, and lasts above double the time; the quantity of paper produced is doubled; and, taking into consideration the work which is now performed by the men over and above their immediate attendance upon the machine, it may be fairly stated, that the number of men is reduced to one half; consequently the expense of wire and labor is reduced to one fourth of what it was.

"The other advantages incidental to the nature of the process of making paper by this machine, may be classed in the following order:—

"1st. That the paper is much superior in strength, firmness, and appearance, to any which can be made by hand of the same material.

"2d. It requires less drying, less pressing and parting, and consequently comes sooner to market; for it receives a much harder pressure from the machine than can possibly be given by any vat press, and is therefore not only drier, but, on account of the closeness and firmness of texture, even the moisture which remains is far sooner evaporated, on exposure to the air, than it would be from the more spongy or bibulous paper made by hand.

"The superior pressure, and the circumstance of one side of the paper passing under the polished surface of one of the pressing rollers, contribute to that smoothness which in hand-made papers can only be obtained by repeated parting and pressing; consequently; a great part of the time necessarily spent in these operations is saved, and the paper sooner finished and ready for market.

"3dly. The quantity of broken paper and retree is almost nothing compared with what is made at the vats.

"4th. The machine makes paper with cold water.

"5th. It is durable, and little subject to be out of repair. The machine at Two Waters, in Hertfordshire, for the last three years, has not cost 10*l.* a year in repairs.

"6th. As paper mills are almost universally wrought by streams, which vary considerably in their power from time to time, there will result from this circumstance a very important advantage in the adoption of the machine. The common paper mill being limited by its number of vats, no advantage can be taken of the frequent accessions of power which generally happen in the course of the year; but, on the contrary, as scarcely any mills are capable of preparing stuff for twelve vats, every accession of power to the mill, where a machine is employed, will increase its produce without any additional expense.

"7th. The manufacturer can suspend or resume his work at pleasure; and he is besides effectually relieved from the perplexing difficulties and loss consequent upon the perpetual combinations for the increase of wages."

It is a lamentable fact, that the attention required to mature this valuable invention, and the large capital which it absorbed, led ultimately to the bankruptcy of this opulent and public-spirited company; after which disaster no patent dues were collected, though twelve suits in Chancery were instituted; these being mostly unsuccessful, on account of some paltry technical objections made to their well-specified patent, by that unscientific judge Lord Tenterden. The piratical tricks practised by many considerable paper-makers against the patentees are humiliating to human nature in a civilized and *soci-disant* Christian community. Many of them have owned, since the bankruptcy of the house removed the fear of prosecution, that they owed them from 2000*l.* to 3000*l.* apiece.

Nothing can place the advantage of the Fourdrinier machine in a stronger point of view, than the fact of there being 280 of them now at work in the United Kingdom, making collectively 1600 miles of paper, of from 4 to 5 feet broad, every day; that they have lowered the price of paper 50 per cent., and that they have increased the revenue, directly and indirectly, by a sum of probably 400,000*l.* per annum. The tissue paper made by the machine is particularly useful for communicating engraved impressions to pottery ware; before the introduction of which there was but a miserable substitute. Messrs. R. and J. Clewes, of Cobridge potteries, in a letter to Messrs. Fourdrinier, state, "that had not an improvement taken place in the manufacture of paper, the new style of engraving would have been of no use, as the paper previously used was of too coarse a nature to draw from the fair engravings any thing like a clear or perfect impression; and the Staffordshire potteries, in our opinion, as well as the public at large, are deeply indebted to you for the astonishing improvement that has recently taken place, both as regards china and earthenware, more particularly the latter." The following rates of prices justify the above statement:—

	1814.		1822.		1833.	
	s.	d.	s.	d.	s.	d.
Demy pottery tissue	-	-	12	0	9	6
Royal	-	-	16	3	12	0

"We have adopted a new mode of printing on china and earthenware, which, but for your improved system of making tissue paper, must have utterly failed; our patent machine requiring the paper in such lengths as were impossible to make on the old plan. On referring to our present stock, we find we have one sheet of your paper more than 1200 yards long. Signed, Machin and Potts; Burslem, February 25th, 1834."

I have had the pleasure of visiting more than once the mechanical workshops of Messrs. Bryan Donkin and Co. in Bermondsey, and have never witnessed a more admirable assortment of exquisite and expensive tools, each adapted to perform its part with despatch and mathematical exactness, though I have seen probably the best machine factories of this country and the Continent. The man of science will appreciate this statement, and may perhaps be surprised to learn that the grand mural circle of 7 feet diameter, made by Troughton, for the Royal Observatory of Greenwich, was turned with final truth upon a noble lathe in the said establishment. It has supplied no fewer than 133 complete automatic paper machines, each of a value of from 1200*l.* to 2000*l.*, to different manufactories, not only in the United Kingdom, but in all parts of the civilized world; as mentioned in the second paragraph of the present article. Each

machine is capable of making, under the impulsion of any prime mover, all unwatched by a human eye, and unguided by a human hand, from 20 to 50 feet in length, by 5 feet broad, of most equable paper in one minute. Of paper of average thickness, it turns off 30 feet.

Fig. 1038 is an upright longitudinal section, representing the machine in its most complete state, including the drying steam cylinders, and the compound channelled rollers of Mr. Wilks, subsequently to be described in detail. The figure in the upper line shows it all in train, when the paper is to be wound up wet upon the reels *x, x*, which being moveable round the centre *l* of a swing-bar, are presented empty, time about, to receive the tender web. The figure in the under line contains the steam or drying cylinders; the points *o o*, of whose frame, replace, at the points *r, r*, the wet reel frame, *r r, r*.

A is the vat, or receiver of pulp from the stuff-chest.

a is the knot strainer of Ibbotson (p. 341.), to clean the pulp before passing on to the wire.

g is the hog, or agitator in the vat. The arrows show the course of the currents of the pulp in the vat.

i is the apron, or receiver of the water and pulp which escape through the endless wire, and which are returned by a scoop-wheel into the vat.

b is the copper lip of the vat, over which the pulp flows to the endless wire, on a leathern apron extending from this lip to about nine inches over the wire, to support the pulp and prevent its escaping.

c, c are the bars which bear up the small tube rollers that support the wire.

d, d are ruler bars to support the copper rollers over which the wire revolves.

k is the breast roller, round which the endless wire turns.

n is the point where the shaking motion is given to the machine.

m is the guide roller, having its pivots moveable laterally to adjust the wire and keep it parallel.

l is the pulp roller, or, "dandy," to press out water, and to set the paper. *r, r* is the place of the second, when it is used.

H is the first or wet press, or couching rollers; the wire leaves the paper here, which latter is couched upon the endless felt *p*; and the endless wire *o* returns, passing round the lower couch roller. By Mr. Donkin's happy invention of placing these rollers obliquely, the water runs freely away, which it did not do when their axes were in a vertical line.

e, e are the deckles, which form the edges of the sheet of paper, and prevent the pulp passing away laterally. They regulate the width of the endless sheet.

f, f are the revolving deckle straps.

n is the deckle guide, or driving-pulley.

g, g are tube rollers, over which the wire passes, which do not partake of the shaking motion; and,

n, h are moveable rollers for stretching the wire, or brass carriages for keeping the rollers g, g in a proper position.

c is the second press, or dry press, to expel the water in a cold state.

κ, κ , &c., in the view of the lower line, are the steam cylinders for drying the endless sheet.

i, i are rollers to convey the paper.

j, j are rollers to conduct the felt; which serves to support the paper, and prevent it wrinkling or becoming cockled.

v, v are the hexagonal expanding reels for the steam-dried paper web, one only being used at a time, and made to suit different sizes of sheets. l is their swing fulcrum.

F, F, F, F , is the frame of the machine.

The deckle straps are worthy of particular notice in this beautiful machine. They are composed of many layers of cotton tape, each one inch broad, and together one half inch thick, cemented with caoutchouc, so as to be at once perfectly flexible and water-tight.

The upper end of each of the two carriages of the roller z is of a forked shape, and the pivots of the roller are made to turn in the cleft of the forked carriages in such a manner, that the roller may be prevented from having any lateral motion, while it possesses a free vibratory motion upwards and downwards; the whole weight of the roller z being borne by the endless web of woven wire.

The greatest difficulty formerly experienced in the paper manufacture upon the continuous system of Fourdrinier, was to remove the moisture from the pulp, and condense it with sufficient rapidity, so as to prevent its becoming what is called *water-galled*, and to permit the web to proceed directly to the drying cylinders. Hitherto no invention has answered so well in practice to remove this difficulty as the channelled and perforated pulp rollers or dandies of Mr. John Wilks, the ingenious partner of Mr. Donkin; for which a patent was obtained in 1830. Suppose one of these rollers (see z , in *fig. 1038* and m, m , in *fig. 1043*) is required for a machine which is to make paper 54 inches wide, it must be about 60 inches long, so that its extremities (see *figs. 1039* and *1040*) may extend over or beyond each edge of the sheet of paper upon which it is laid. Its diameter may be 7 inches. About 8 grooves, each 1-16th of an inch wide, are made in every inch of the tube; and they are cut to half the thickness of the copper, with a rectangularly shaped tool. A succession of ribs and grooves are thus formed throughout the whole length of the tube. A similar succession is then made across the former, but of 24 in the inch, and on the opposite surface of the metal, which by a peculiar mode of management had been prepared for that purpose. As the latter grooves are cut as deep as the former, those on the inside meet those on the outside, crossing each other at right angles, and thereby producing so many square holes; leaving a series of straight copper ribs on the interior surface of the said tube, traversed by another series of ribs coiled round them on the outside, forming a cylindrical sieve made of one piece of metal. The rough edges of all the ribs must be rounded off with a smooth file into a semi-circular form. *Figs. 1039*, and *1040*. A, A , are portions of the ribbed copper tube. *Fig. 1039* shows the exterior, and *fig. 1040* the interior surface; b, b and b, b show the plain part at each of the ends, where it is made fast to the brass rings by rivets or screws; c, c are the rings with arms, and a centre piece in each, for fixing the iron pivot or shaft n ; one such pivot is fixed by riveting it in each of the centre pieces of the rings, as shown at c , *fig. 1040*; so that both the said pieces shall be concentric with the rings, and have one common axis with each other, and with the roller. At a, a , a groove is turned in each of the pivots, for the purpose of suspending a weight by a hook, in order to increase the pressure upon the paper, whenever it may be found necessary.

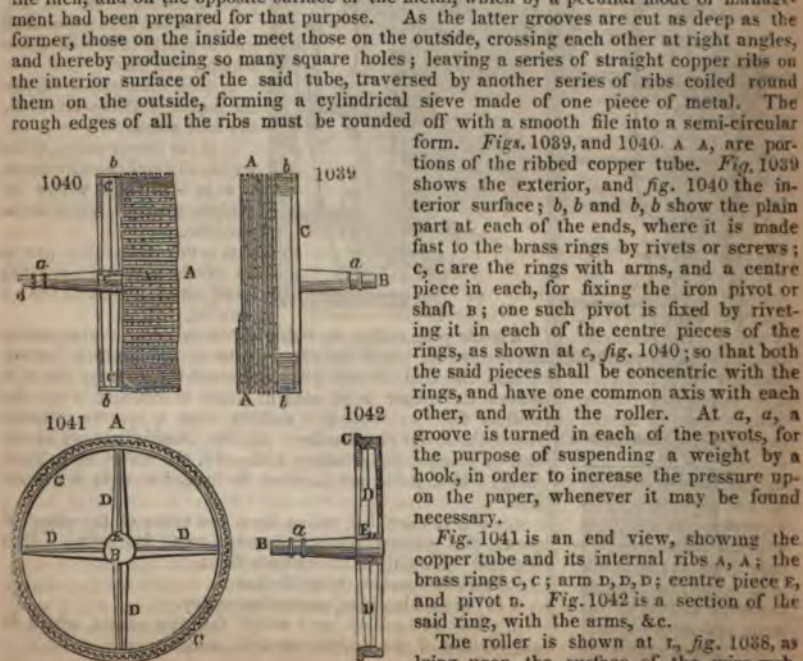

Fig. 1041 is an end view, showing the copper tube and its internal ribs A, A ; the brass rings c, c ; arm D, D, D ; centre piece B , and pivot n . *Fig. 1042* is a section of the said ring, with the arms, &c.

The roller is shown at z , *fig. 1038*, as lying upon the surface of the wire-web.

The relative position of that perforated roller, and the little roller *b*, over which it lies, is such that the axis of *l* is a little to one side of the axis of *b*, and not in the same vertical plane, the latter being about an inch nearer the vat end. Hence, whenever the wire-web is set in progressive motion, it will cause the roller *l* to revolve upon its surface; and as the paper is progressively made, it will pass onwards with the web under the surface of the roller. Thus the pulpy layer of paper is condensed by compression under the ribbed roller; while it transmits its moisture through the perforations, it becomes sufficiently compact to endure the action of the wet press rollers *h, h*, and also acquires the appearance of parallel lines, as if made by hand in a laid mould.

Mr. Wilks occasionally employs a second perforated roller in the same paper machine, which is then placed at the dotted lines *i, i, i*.

The patentee has described in the same specification a most ingenious modification of the said roller, by which he can exhaust the air from a hollowed portion of its periphery, and cause the paper in its passage over the roller to undergo the sucking operation of the partial void, so as to be remarkably condensed; but he has not been called upon to apply this second invention, in consequence of the perfect success which he has experienced in the working of the first.

The following is a more detailed illustration of Mr. Wilks' improved roller.

Fig. 1043 represents two parts of his double-cased exhausting cylinder.

This consists of two copper tubes, one nicely lining the other; the inner being punched full of round holes, as at *k, k*, where that tube is shown uncovered; a portion of the inner surface of the same tube is shown at *l, l*. In this figure also, two portions of the outer tube are shown at *m, m*, and *n, n*; the former being an external, and the latter an internal view. Here we see that the external tube is the ribbed perforated one already described; the holes in the inner tube being made in rows to correspond with the grooves in the outer. The holes are so distributed that every hole in one row shall be opposite to the middle of the space left between two holes in the next row, as will appear from inspection of the figure. The diameter of each of the punched holes somewhat exceeds the width of each rib in the inside of the outer cylinder, and every inside groove of this tube coincides with a row of holes in the former, which construction permits the free transudation or perco-

ration of the water out of the pulp. At each end of this double-case cylinder, a part is left at *n, n*, plain without, and grooved merely in the inside of the outer tube. The smooth surface allows the brass ends to be securely fixed; the outer edge of the brass ring fits tight into the inside of the end of the cylinders.

On the inside of each of these rings there are four pieces which project towards the centre or axis of the cylinder; two of which pieces are shown at *a, a*, fig. 1043 in section. *b, b*, is a brass ring with four arms *c, c, c, c*, and a boss or centre piece *d, d*. The outer edge of the last-mentioned ring is also turned cylindrical, and of such a diameter as to fit the interior of the former ring *a, a*. The two rings are securely held together by four screws. *e, e* is the hollow iron axle or shaft upon which the cylinder revolves. Its outside is made truly cylindrical, so as to fit the circular holes in the bosses *d, d*, of the rings and arms at each end of the cylinder. Hence, if the hollow shaft be so fixed that it will not turn, the perforated cylinder is capable of having a rotatory motion given to it round that shaft. This motion is had recourse to, when the vacuum apparatus is employed. But otherwise the cylinder is made fast to the hollow axle by means of two screw clamps. To one end of the cylinder, as at *p*, a toothed wheel is attached, for communicating a rotatory motion to it, so that its surface motion shall be the same as that of the paper web; otherwise a rubbing motion might ensue, which would wear and injure both.

The paper stuff or pulp is allowed to flow from the vat *a*, fig. 1038 on to the surface of the endless wire-web, as this is moving along. The lines *o, o*, fig. 1038 show the course of

the motion of the web, which operates as a sieve, separating to a certain degree the water from the pulp, yet leaving the latter in a wet state till it arrives at the first pair of pressing rollers *H, H*, between which the web with its sheet of paper is squeezed. Thick paper, in passing through these rollers, was formerly often injured by becoming water-galled, from the greater retention of water in certain places than in others. But Messrs. Donkin's cylinder, as above described, has facilitated vastly the discharge of the water, and enabled the manufacturer to turn off a perfectly uniform smooth paper.

In *fig. 788*, immediately below the perforated cylinder, there is a wooden water-trough. Along one side of the trough a copper pipe is laid, of the same length as the cylinder, and parallel to it; the distance between them being about one fourth of an inch. The side of the pipe facing the cylinder is perforated with a line of small holes, which transmit a great many jets of water against the surface of the cylinder, in order to wash it and keep it clean during the whole continuance of the process.

The principle adopted by John Dickinson, Esq., of Nash Mill, for making paper, is different from that of Fourdrinier. It consists in causing a polished hollow brass cylinder, perforated with holes or slits, and covered with wire cloth, to revolve over and just in contact with the prepared pulp: so that by connecting the cylinder with a vessel exhausted of its air, the film of pulp, which adheres to the cylinder during its rotation, becomes gently pressed, whereby the paper is supposed to be rendered drier, and of more uniform thickness, than upon the horizontal hand moulds, or travelling wire cloth of Fourdrinier. When subjected merely to agitation, the water is sucked inwards through the cylindric cage, leaving the textile filaments so completely interwoven as, if felted among each other, that they will not separate without breaking, and, when dry, they will form a sheet of paper of a strength and quality relative to the nature and preparation of the pulp. The roll of paper thus formed upon the hollow cylinder is turned off continuously upon a second solid one covered with felt, upon which it is condensed by the pressure of a third revolving cylinder, and is thence delivered to the drying rollers.

Such is the general plan of Mr. Dickinson's paper machines, into which he has introduced numerous improvements since its invention in 1809, many of them secured by patent right; whereby he has been enabled to make papers of first-rate quality, more particularly for the printing-press. See *infra*.

In July, 1830, Mr. Ibotson of Poyle, paper manufacturer, obtained a patent, see *n. fig. 788*, which has proved very successful, for a peculiar construction of a sieve or strainer. Instead of wire meshes, he uses a series of bars of gun-metal, laid in the bottom of a box, very closely together, so that the upper surfaces or the flat sides may be in the same plane, the edge of each bar being parallel with its neighbor, leaving parallel slits between them of from about 1-70th to 1-100th of an inch in width, according to the fineness or coarseness of the paper-stuff to be strained. As this stuff is known to consist of an assemblage of very fine flexible fibres of hemp, flax, cotton, &c., mixed with water, and as, even in the pulp of which the best paper is made, the length of the said fibres considerably exceeds the diameter of the meshes of which common strainers are formed, consequently the longest and most useful fibres were formerly lost to the paper manufacturer. Mr. Ibotson's improved sieve is employed to strain the paper-stuff previously to its being used in the machine above described, (see its place at *n* in the *vat*.) When the strainer is at work, a quick vertical and lateral jogging motion is given to it, by machinery similar to the jogging screens of corn mills.

Since the lateral shaking motion of the wire-web in the Fourdrinier machine, as originally made, was injurious to the fabric of the paper, by bringing its fibres more closely together breadthwise than lengthwise, thus tending to produce long ribs, or thick streaks in its substance, Mr. George Dickinson, of Buckland Mill, near Dover, proposed, in the specification of a patent obtained in February, 1828, to give a rapid up-and-down movement to the travelling web of pulp. He does not, however, define with much precision any proper mechanism for effecting this purpose, but claims every plan which may answer this end. He proposes generally to mount the rollers, which conduct the horizontal endless web, upon a vibrating frame. The forepart of this frame is attached to the standards of the machine, by hinge joints, and the hinder part, or that upon which the pulp is first poured out, is supported by vertical rods, connected with a crank on a shaft below. Rapid rotatory motion being given to this crank-shaft, the hinder part of the frame necessarily receives a quick up-and-down vibratory movement, which causes the water to be shaken out from the web of pulp, and thus sets the fibres of the paper with much greater equality than in the machines formerly constructed. A plan similar to this was long ago introduced into Mr. Donkin's machines, in which the vibrations were actuated in a much more mechanical way.

John Dickinson, Esq., of Nash Mill, obtained a patent in October, 1830, for a method of uniting face to face two sheets of pulp by means of machinery, in order to produce paper

of extraordinary thickness. Two vats are to be supplied with paper stuff as usual; in which two hollow barrels or drums are made to revolve upon axles driven by any first mover; an endless felt is conducted by guide rollers, and brought into contact with the drums; the first drum gives off the sheet of paper pulp from its periphery to the felt, which passing over a pressing roller, is conducted by the felt to that part of a second drum which is in contact with another pressing roller. A similar sheet of paper pulp is now given off from the second drum, and it is brought into contact with the former by the pressure of its own roller. The two sheets of paper pulp thus united are carried forward by the felt over a guide roller, and onward to a pair of pressing rollers, where by contact the moist surfaces of the pulp are made to adhere, and to constitute one double thick sheet of paper, which, after passing over the surfaces of hollow drums, heated by steam, becomes dry and compact. The rotatory movements of the two pulp-lifting drums must obviously be simultaneous, but that of the pressing rollers should be a little faster, because the sheets extend by the pressure, and they should be drawn forward as fast as they are delivered, otherwise creases would be formed. Upon this invention is founded Mr. Dickinson's ingenious method of making safety-paper for Post-office stamps, by introducing silk fibres, &c., between the two laminæ.

The following contrivance of the same inventive manufacturer is a peculiarly elegant mechanical arrangement, and is likely to conduce to the perfection of machine-made paper. I have already described Mr. Ibotson's excellent plan of parallel slits, or gridiron strainers, which has been found to form paper of superior quality, because it permits all the elongated tenacious fibres to pass, which give strength to the paper, while it intercepts the coarser knots and lumps of the paste, that were apt to spoil its surface. Mr. Turner's circular wire sieves, presently to be noticed, may do good work, but they cannot compete with Mr. Dickinson's present invention, which consists in causing the diluted paper pulp to pass between longitudinal apertures, about the hundred-and-fifteenth part of an inch wide, upon the surface of a revolving cylinder.

The pulp being diluted to a consistency suitable for the paper machine, is delivered into a vat, of which the level is regulated by a waste pipe, so as to keep it nearly full. From this vat there is no other outlet for the pulp, except through the wire-work periphery of the revolving cylinder, and thence out of each of its ends into troughs placed alongside, from which it is conducted to the machine destined to convert it into a paper web.

The revolving cylinder is constructed somewhat like a squirrel cage, of circular rods, or an endless spiral wire, strengthened by transverse metallic bars, and so formed that the spaces between the rings are sufficient to allow the slender fibres of the pulp to pass through, but are narrow enough to intercept the knots and other coarse impurities, which must of course remain, and accumulate in the vat. The spaces between the wires of the squirrel cage may vary from the interval above stated, which is intended for the finest paper, to double the distance for the coarser kinds.

It has been stated that the pulp enters the revolving cylinders solely through the intervals of the wires in the circumference of the cylinder; these wires or rods are about three eighths of an inch broad without, and two eighths within, so that the circular slits diverge internally. The rods are one quarter of an inch thick, and are riveted to the transverse bars in each quadrant of their revolution, as well as at their ends to the necks of the cylinder.

During the rotation of the cylinder, its interstices would soon get clogged with the pulp, were not a contrivance introduced for creating a continual vertical agitation in the inside of the cylinder. This is effected by the up-and-down motion of an interior agitator or plunger, nearly long enough to reach from the one end of the cylinder to the other, made of stout copper, and hollow, but water-tight. A metal bar passes through it, to whose projecting arm at each end a strong link is fixed; by these two links it is hung to two levers, in such a way that when the levers move up and down, they raise and depress the agitator, but they can never make it strike the sides of the cylinder. Being heavier than its own bulk of water, the agitator, after being lifted by the levers, sinks suddenly afterwards by its weight alone.

The agitator's range of up-and-down movement should be about one inch and a quarter, and the number of its vibrations about 80 or 100 per minute; the flow of the pulp through the apertures is suddenly checked in its descent and promoted in its ascent, with the effect of counteracting obstructions between the ribs of the cylinder.

The sieve cylinder has a toothed wheel fixed upon the tubular part of one of its ends, which works between two metal flanches made fast to the wooden side of the vat, for the purpose of keeping the pulp away from the wheel; and it is made to revolve by a pinion fixed on a spindle, which going across the vat, is secured by two plummer blocks on the outside of the troughs, and has a rotatory motion given to it by an outside rigger or pulley, by means of a strap from the driving shaft, at the rate of 40 or 50 revolutions

per minute. This spindle has also two double eccentrics fixed upon it, immediately under the levers, so that in every revolution it lifts those levers twice, and at the same time lifts the agitator.

The diameter of the sieve cylinder is not very material, but 14 inches have been found a convenient size; its length must be regulated according to the magnitude of the machine which it is destined to supply with pulp. One, four feet long in the cage part, is sufficient to supply a machine of the largest size in ordinary use, viz., one capable of making paper 4 feet 6 inches wide. When the cylinder is of this length, it should have a wheel and pinion at each end.

Metal flanges are firmly fixed to the sides of the vat, with a water-tight joint, and form the bearings in which the cylinder works.

Mr. Turner of Bermondsey, paper-maker, obtained a patent in March, 1831, for a peculiar strainer, designed to arrest the lumps mixed with the finer paper pulp, whereby he can dispense with the usual vat and hog in which the pulp is agitated immediately before it is floated upon the endless wire-web of the Fourdrinier apparatus. His strainer may also be applied advantageously to hand paper machines. He constructs his sieves of a circular form, by combining any desirable number of concentric rings of metal, with small openings between them, from the 50th to the 100th part of an inch wide. In order to facilitate the passage of the fine pulp and water, the sieves receive a vibratory motion up and down, which supersedes the hog employed in other paper-making machines.

A mechanism to serve the same purpose as the preceding, in which Mr. Ibotson's plan of a parallel rod-strainer is modified, was made the subject of a patent by Mr. Henry Brewer, of Surrey Place, Southwark, in March, 1832. He constructs square boxes with gridiron bottoms, and gives a powerful up-and-down vibration in the pulp tub, by levers, rotatory shafts, and cranks.

As the contrivance is not deficient in ingenuity, and may be useful, I shall describe this mode of adapting his improved strainers to a vat in which paper is to be made by hand moulds. A hog (or churning rotator) is employed for the purpose of agitating the pulp at the bottom of the vat, in which the sieve is suspended from a crank-shaft, or in any other way, so as to receive the up-and-down vibratory motion for the purpose of straining the pulp. The pulp may be supplied from a chest, and passed through a cock into a trough, by which it is conveyed to the strainers.

A pipe from the bottom of the vat leads into a lifter-box, which is designed to convey thin pulp into the sieve, in order to dilute that which is delivered from the chest. This pipe also allows the small lumps, called rolls, to be re-sifted. The pressure of the pulp and water in the vat forces the pulp up the pipe into the lifter-box, whence it is taken by rotatory lifters, and discharged into a trough, where it runs down and mixes with the thick pulp from the chest, as before mentioned. By these means the contents of the vat are completely strained or sifted over again in the course of almost every hour.

A patent was obtained for a paper-pulp strainer by Mr. Joseph Amies, of Loose, in the county of Kent, paper manufacturer, who makes the bottoms of his improved strainers with plates of brass or other suitable metal, and forms the apertures for the fine fibres of pulp to pass through, by cutting short slits through such plates, taking care that as much metal is left between the ends of each short slit and the next following as will properly brace or stiffen the ribs of the strainer; and he prefers that the end of one slit shall be nearly opposite to the middle of the two slits next adjoining it, which is commonly called blocking the joints. This is for giving rigidity to the bottom of the strainer, and constitutes the main feature of his improvement. The bottoms of sieves previously constructed with long metallic rods, he considers to be liable to lateral vibration in use, and thus to have permitted knots and lumps to pass through their expanded intervals. This objection is not applicable to Mr. Dickinson's squirrel-cage strainer, of which the ribs may be made rigid by a sufficient number of transverse bars; nor in fact is it applicable to Mr. Ibotson's original strainer, as it is admirably constructed by Messrs. Donkin and Co. Each bar which they make being inflexible by a feathered rib, is rendered perfectly straight in its edge by grinding with emery upon a flat disc-wheel of block tin, and of invariable length, by a most ingenious method of turning each set of bars in a lathe. The bars are afterwards adjusted in the metallic sieve-frame, or chest, at any desired distance apart, from the 120th to the 60th of an inch, in such a manner as secures them from all risk of derangement by the vibratory or jogging motion in shaking the pulpy fibres through the lineal intervals between them.

Mr. James Brown, paper manufacturer, of Esk mills, near Edinburgh, obtained a patent in May, 1836, for a particular mode of applying suction to the pasty web in the Fourdrinier's machine. He places a rectangular box transversely beneath the horizontal wire cloth, without the interposition of any perforated covering, such as had been

tried in the previously constructed vacuum machines, and which he considers to have impeded their efficacy in condensing the pulp and extracting the water.

Upon this and all similar contrivances for making a partial vacuum under the pulpy paper web, it may be justly remarked, that they are more apt to injure than improve the texture of the article; since when the suction is unequally operative, it draws down not only the moisture, but many of the vegetable fibres, causing roughnesses, and even numerous small perforations in the paper.

A modification of Mr. Dickinson's cylinder-mould continuous paper machine was made the subject of a patent in Nov. 1830, by Mr. John Hall, jun., of Dartford, as communicated to him by a foreigner residing abroad. The leading feature of the invention is a mode of supplying the vat in which the wire cylinder is immersed with a copious flow of water, for the purpose of creating a considerable pressure upon the external surface of the cylinder, and thereby causing the fibres of the paper pulp to adhere to the mould.

There is a semi-cylindrical trough, in which the mould is immersed, and made to revolve by any convenient means. The pulp is transferred from the vat into that vessel at its bottom part. On the side of the drum-mould opposite to the vat, there is a cistern into which a copious flow of water is delivered, which passes thence into the semi-cylindrical trough. In the interior of the cylindrical mould, a bent or syphon tube is introduced, on the horizontal part of which tube, inside, the mould revolves. This tube is connected at the outside to a pump, by which the water is drawn from the interior of the cylindrical mould. Thus the water in the semi-cylindrical trough, on the outside of the drum, is kept at a considerably higher level than it is within; and consequently the pressure of the water, as it passes through the wire gauze, will, it is supposed, cause the fibres of the paper pulp to adhere to the circumference of the mould. The water which is withdrawn from the interior of the drum by the recurved tube, is conducted round into the cistern, where its discharge is impeded by several vertical partitions, which make the water flow in a gentle stream into the semi-cylindrical mould vat. In order to keep the pulp properly agitated in the mould vat, a segment frame, having rails extended across the vat, is moved to and fro; as the drum mould goes round, the fibres of the pulp are forced against its circumference, and as the water passes through, the fibres adhere, forming the sheet of paper, which, on arriving at a couching roller above, is taken up as usual by an endless felt, conducted away to the drying apparatus, and thence to the reel to be wound up.

The patentee claims merely the application of a pump to draw the water from the interior of the mould drum, and to throw it upon its external surface.

A rag-cutting and lacerating machine was patented by Mr. Henry Davy, of Camberwell, in September, 1833, being a communication from a foreigner residing abroad. The machine consists of an endless feeding-cloth, by which the rough rags supplied by the attendants are progressively conducted forwards to a pair of feed-rollers (see *COTTON, spinning*), and on passing through these rollers, the rags are subjected to the operation of rotatory cutters, acting against a fixed or ledger blade, which cut and tear them to pieces. Thence the rags pass down an inclined sieve, upon which they are agitated to separate the dust. The cleaned fragments are delivered on to a horizontal screen or sorting table, to suffer examination. When picked here, they are ready for the pulp-engine. A distinct representation of this machine is given in *Newton's Journal*, conjoined series, vol. iv. pl. ix. fig. 1.

Mr. Jean Jacques Jequier obtained a patent in August, 1831, for a mode of making paper on the continuous machine with wire-marks. The proposed improvement consists merely in the introduction of a felted pressing roller, to act upon the paper after it has been discharged from the mould, and need not therefore be particularly described.

In August, 1830, Mr. Thomas Barratt, paper-maker, of St. Mary Cray, in the county of Kent, obtained a patent for an apparatus by which paper may be manufactured in a continuous sheet, with the water-mark and maker's name, so as to resemble in every respect paper made by hand, in moulds the size of each separate sheet. On the wire web, at equal distances apart, repetitions of the maker's name or other device is placed, according to the size of the paper when cut up into single sheets. In manufacturing such paper, the ordinary method of winding upon a reel cannot be employed; and therefore the patentee has contrived a compensating reel, whose diameter diminishes at each revolution, equal to the thickness of a sheet of paper. See *Newton's Journal*, C. S. vol. vii. p. 285.

For Mr. Lemuel Wellman Wright's series of improvements in the manufacture of paper, specified in his patent of November, 1834, I must refer to the above *Journal*, C. S., vol. viii. p. 86.

A committee of the *Société d'Encouragement*, of Paris, made researches upon the best composition for sizing paper in the vat, and gave the following recipe:—

PAPER, SIZING OF.

100 kilogrammes of dry paper stuff.

12 — starch.

1 — rosin, previously dissolved in 500 grammes
of carbonate of soda.

18 pails of water.

M. Braconnot proposed the following formula in the 23d volume of the *Annales de Chimie et de Physique*:—To 100 parts of dry stuff, properly diffused through water, add a boiling uniform solution of 8 parts of flour, with as much caustic potash as will render the liquor clear. Add to it one part of white soap previously dissolved in hot water. At the same time heat half a part of rosin with the requisite quantity of weak potash ley for dissolving the rosin; mix both solutions together, and pour into them one part of alum dissolved in a little water.

Those who color prints, size them previously with the following composition:—4 ounces of glue, and 4 ounces of white soap dissolved in 3 English pints of hot water. When the solution is complete, two ounces of pounded alum must be added, and as soon as the composition is made homogeneous by stirring, it is ready for use. It is applied cold with a sponge, or rather with a flat camel's hair brush. Ackermann's liquor, as analyzed by Vanquelin, may be made for sizing paper as follows:—

100 kilogrammes of dry stuff.

4 — glue.

8 — resinous soap.

8 — alum.

The soap is made from 4.8 kilos. of pounded rosin, and 2.22 crystals of carbonate of soda, dissolved in 100 litres of water. It is then boiled till the mixture becomes quite uniform; the glue, previously softened by 12 hours' maceration in cold water, is to be next added; and when this is totally dissolved, the solution of alum in hot water is poured in. Three quarts of this size were introduced into the vat with the stuff, and well mixed with it. The paper manufactured with this paste seemed to be of excellent quality, and well sized.

The Chinese, in manufacturing paper, sometimes employ linen rags, as we do; at other times, the fibres of the young bamboo; of the mulberry; the envelope of the silk-worm cocoon; also a tree, unknown to our botanists, which the natives call *chu* or *leo-chu*; cotton down, and especially the cotton tree. The processes pursued in China to make paper with the inner bark of their *paper-tree* (*Broussonetia papyrifera*), or Chinese mulberry, have been described at great length in the bulletin of the Société d'Encouragement, for 1826, p. 226; but they will hardly prove serviceable to a European manufacturer. That tree has been acclimated in France.

Chinese paper is not so well made as the good paper of Europe; it is not so white, it is thinner, and more brittle, but extremely soft and silky. The longitudinal tenacity of its filaments, however, renders it fitter for the engraver than our best paper. The Chinese, after triturating, grinding, and boiling the bamboo, set the paste to ferment in a heap covered with mats. Chinese paper is readily recognised, because it is smooth on one side, and bears on the other the marks of the brush with which it is finished, upon smooth tables, in order to dry it flat. The kind employed for engravings is in sheets four feet long, and two broad. It is made of the bamboo; their myrtle-tree paper would be too strong for this purpose.

Paper, sizing of. Mr. John Dickinson obtained a patent, in 1840, for a mode of sizing paper continuously in a vessel partially exhausted of air, by unwinding a scroll of dried paper from a reel, and conducting it through heated size; then after pressing out the superfluous size, winding the paper on to another reel; in the course of which final progress it is dried by steam heat.—*Newton's Journal*, xxiii. 20.

Tracing Paper.

The best paper of this kind, sometimes superfluously called vegetable paper, is made of the refuse of the flax mills, and prepared by the engine without fermentation. It thus forms a semi-transparent paste, and affords a transparent paper. Bank-note paper is made of the same materials, but they always undergo a bleaching with chloride of lime. Great nicety is required in drying this kind of paper. For this purpose, each sheet must be put between two sheets of gray paper in the press; and this gray paper must be renewed several times, to prevent the bank-note paper from creasing.

Paper of Safety or Surety; Papier de Sureté.

This subject has occupied the attention of the French Academy for many years, in consequence of the number of frauds committed upon the stamp revenue in France. One of the best methods of making a paper which would evince whether any part of a writing traced upon it had been tampered with or discharged, is to mix in the vat

two kinds of pulp, the one perfectly white, the other dyed of any colour easily affected by chlorine, acids, and alkalis. The latter stuff being mingled with the former in any desired proportion, will furnish a material for making a paper which will contain coloured points distributed throughout all its substance, ready to show, by the changes they suffer, whether any chemical reaction has been employed.

PAPER. The construction of wire-web cylinders for paper-making machines, and the combination of two such cylinders in one machine, by the use of which two distinct thicknesses of paper pulp are obtained, and applied face-wise, to form one thick sheet, were made the subject of a patent under the name of John Donkin. Two cylinders are so placed in a vat that their circumferences are nearly in contact, and by being turned in opposite directions, they bring two sheets of paper pulp into contact, and incorporate them into one, by what is technically termed *couching*.

An extensive patent for improvements in the manufacture of paper was granted to Charles Edward Amos in 1840. These consist, first, in gradually lowering the roll of the engine in which the rags are prepared and converted into pulp; secondly, in a mode of regulating the supply of pulp to the paper-making machine, in order to produce papers of any required thickness; thirdly, in an improved sifter or strainer through which the pulp is passed for clearing it of knobs and lumps; fourthly, in certain modifications of the parts of the machine in which the pulp is deposited and moulded into continuous lengths of paper; fifthly, in an improved method of heating the cylinders of the drying apparatus; and, sixthly, in improvements of the machinery for cutting the paper into sheets of any required dimensions. The details of these ingenious contrivances, illustrated with engravings, are given in *Newton's Journal*, xx., p. 153., C. S.

Henry Crossley purposes to manufacture paper from waste tan, and spent hops—with what success I have not heard. Joseph Hughes gives a higher finish to the long web of paper by friction between two cylinders, the one of which moves much quicker than the other, both being covered with felt or not, at pleasure.

Mr. John Dickinson, the eminent paper manufacturer, obtained a patent in 1840 for a new mode of sizing paper continuously, in an air-tight vessel (partly exhausted of air), by unwinding a scroll of dried paper from a reel, and conducting it through heated size; then, after pressing out the superfluous size, winding the paper on to another reel.

A longitudinal section of the apparatus employed for this purpose is represented *fig. 1044*; where *a* is the air-tight vessel; *b*, the reel upon which the paper to be sized is wound; whence it proceeds beneath the guide-roller *c*, and through the warm size to another guide-roller *d*. It thence ascends between the press-rolls, *e, f* (by whose revolution the paper is drawn from the reel *b*), and is wound upon the reel *g*. A float *h* is suspended from the cross-bar *i*, of the vessel *a*, for the purpose of diminishing the surface of size exposed to evaporation; and beneath the bottom of the vessel is an enclosed space *j*, into which steam or hot water is introduced for maintaining the temperature of the size.—*Newton's Journal*, xxiii. 20.

Messrs. Charles Cowan and Adam Ramage, paper-makers, patented, in 1840, improved rag machinery; in which a cylindrical sieve or strainer of wire-cloth, of a peculiar construction, is substituted for the ordinary strainers, by which the dirty water is separated from the pulp. They do not claim the cylindric form or sieve, but "the adding or applying, and combining within the interior of such drum, scoops, or buckets, for the purpose of elevating the water, which has entered into it through its wire circumference, so that the water when elevated may be able to run by its own gravity out of the hollow around the central axis of the drum into any suitable shoot or trough, and escape at a level above the surface of the water and rags or material contained in the paper-machine."

Thomas Barrett claims, in his patent of 1841, "a mode of drying paper by applying streams of air to its two surfaces, as it passes over the steam cylinders, whether in the state of engine size or water leaf, or after sizing; as also, the application of currents of air to the surfaces of paper, after sizing, in order to cool the size; as the paper is passing to the drying cylinders."

The improvements in paper-making, for which T. W. Wrigley, of Bridge Hall Mills, Bury, obtained a patent in 1842, relate to the rag engine, *figs.* 1045, 1046, 1047

1048. *Fig.* 1045 is a side elevation; *fig.* 1046, a transverse section, taken lengthwise through nearly its middle; *fig.* 1047 a plan view of the apparatus detached upon a

larger scale; and *fig.* 1048 is an elevation. The vessel in which the rags are placed is shown at *a a*, and in about the centre of this vessel the beating or triturating roll, *b, b*, is placed: it is surrounded with the blades or roll bars, *c c*, *fig.* 1046. The roll is mounted upon a shaft, *d d*, one end of which is placed in a pedestal or bearing on the further side of the chamber *a*, and the other in a bearing upon the arm or level *e e*, *fig.* 1045 which is supported by its fulcrum, at the end *e*, in one of the standards, *f f*, and at the other end by a pin fixed in the connecting rod, *g g*. At the upper end of this connecting rod there is a cross-piece, or head *h*, having turned pivots at each end upon which are placed small rollers, *i i*, resting upon a horizontal cam, *k k*, which is made to revolve. This cam, *k k*, by means of its gearing, causes the roll *b* first of all to wash the rags a short time, then to be lowered at whatever rate is desired for breaking the fibres; to be maintained at the lowest point for the required number of revolutions for beating; and to be raised and retained, as required, for the final purpose of

clearing the pulp. The upper or working edge of this cam is to be shaped exactly according to the action required by the engine roll; as, for instance, suppose the previous operation of washing to be completed, and the time required for the operation of the rag machine to be three hours, one of which is required for lowering the roll, that, or the first division of the working surface of the cam, *k k*, must be so sloped or inclined, that, according to the speed at which it is driven, the rollers upon the cross-head shall be exactly that portion of the time descending the incline upon the cam, and consequently lowering the roll upon the plates *n*, fig. 111; and if the second hour shall be required for the roll to beat up the rags, the roll revolving all the time in contact with the plates, the second division of the cam, *k k*, must be so shaped (that is, made level), that the roll shall be allowed to remain, during that period, at its lowest point; and if the third portion of the time, or an hour, be required for raising the roll again, either gradually or interruptedly, then the third division of the cam, *k*, must be suitably shaped or inclined, so as to cause the cross-head to lift the roll during such interval or space of time; the particular shape of the inclined portions of the cam depending on the manner in which the manufacturer may wish the roll to approach to or recede from the bottom plates, during its descent and ascent respectively.

Its mode of connexion and operation in the rag engine is as follows: supposing that the rags intended to be beaten up are placed in the vessel *a*, fig. 111, and motion is communicated, from a steam-engine or other power, to the farther end of the shaft *d*, the roll *b*, will thus be caused to revolve, and the rags washed, broken, and beaten up, as they proceed from the front weir *m*, over the bottom plates *n*, and again round by the back weir *o*. There is a small pulley *p*, upon the near end of the shaft *d*, round which a band *q* passes, and also round another pulley *r*, upon the cross shaft *s*; upon this shaft is a worm *t*, gearing into a worm-wheel *u*, fixed upon another shaft *v*, below; upon the reverse end of which is a pinion *w*, gearing into a spur-wheel *x*, upon the end of a shaft *y*; and upon the centre of this shaft *y*, there is another worm *z*, gearing into a horizontal worm-wheel *1*, upon which the cam, *k k*, is fixed. Thus it will be seen, that the requisite slow motion is communicated to the cam, which may be made to perform half a revolution in three hours; or it will be evident, that half a revolution of the cam, *k k*, may be performed in any other time, according to the calculation of the gearing employed. The shaft may also be driven by hand, so as to give the required motion to the cam. Supposing, now, at the beginning of the operation, the cross head bearing the lever and roll, to be at the highest point upon the cam, *k k*, as its revolution commences, the roll will revolve for a short time on the level surface of the cam, and will then be lowered until the cam, *k k*, has arrived at that point which governs the time that the roll remains at the lowest point, for the purpose of beating the rags into pulp, and as the cam, *k k*, continues to revolve, and thus brings the opposite slope upon the third portion of its working surface into action upon the cross head, the roll will be raised, in order to clear the pulp from knots and other imperfections, and thus complete the operation of the engine. In order to raise the cross head and roll to the height from which it descended without loss of time, or to lift the cross head entirely from off the cam when requisite, a lever, 2, or other suitable contrivance may be attached to the apparatus, also a shaft may be passed across the rag-engine, and both ends of the roll may be raised instead of one only, as above described.

The patentee does not claim as his invention the lowering and raising the roll of the rag-engine, nor the lowering of it by mechanism, as this was effected in Mr. Amos's patent of 1840; but he claims the above peculiar apparatus for this purpose.—*Newton's Journal*, xxiii. 254. C. S.

Quantity of Paper charged with Duties of Excise, in the United Kingdom, in

	1834.	1835.	1836.
	<i>lbs.</i>	<i>lbs.</i>	<i>lbs.</i>
First Class - - - - -	54,053,721	56,179,555	66,202,689

	<i>yards.</i>	<i>yards.</i>	<i>yards.</i>
Stained - - - - -	8,749,144	8,247,931	8,032,557
	£ s. d.	£ s. d.	£ s. d.
Amount of duty, first class,	675,671 10 0	702,244 9 0	651,699 0 0
— second class, -	103,451 0 0	111,644 0 0	99,414 0 0
— pasteboard, &c. -	54,689 0 0	54,548 15 0	39,557 0 0
— stained - - -	63,795 16 0	60,141 0 0	22,112 0 0

The late reduction of the duty, from 3*d* to 1½*d* per lb., upon paper of the first class viz., on all descriptions of it, except that made out of tarred ropes only, has been already attended with considerable benefit to the manufacture, and would have acted with much greater effect, but for the American crisis. The gross amount of the paper duty in the year ending 5th January, 1836, was 831,057*l*., and in the year ending 5th January, 1838, it was 554,497*l*.; instead of being little more than one half, as might have been the case from the reduction of the duty, which only came into full operation in the year 1837. The gross revenue in 1841 was, 633,520*l*., the nett, 583,647*l*.; in 1844, 709,320 gross, 609,906*l*. nett; in 1847, 810,944*l*. gross, 762,172*l*. nett; in 1852, 915,121*l*. gross, 852,966*l*. nett. Paper of all kinds charged with duty in 1850, 925,520*l*. At the same time that the tax on common paper was reduced, that upon stained paper was repealed altogether. The effect of the diminution consequently made in the price of paper-hangings, has been so great as nearly to double the consumption of the country, while the manufacture appears to be still rapidly on the increase.

Declared Value of Stationery and Printed Books exported in

1836	301,121	178,945	480,066

Till the paper trade shall escape entirely from the clutches of its ancient dry-nurse, the excise, neither it nor the book trade can acquire the same ascendancy in exportation which all other articles of British manufactures have over the French.

The Value of Stationery exported in France, from 1833, was,

Cartons lustrés (polished pasteboards for the cloth manufacture)	18,992 francs
Cartons en feuilles (pasteboard in sheets)	6,352 —
Cartons moulés (papier-maché)	215,376 —
Cartons coupés et assemblés	54,184 —
Wrapping paper	178,544 —
White paper, and rayé (ruled) pour musique	2,903,075 —
Coloured paper in reams	58,541 —
Stained paper (paper hangings) in rouleaux	1,885,387 —
Silk paper	3,240 —

Total (—£208,000) 5,323,621 francs

Mr. John Dickinson's invention for sizing paper, continuously, in an air-tight vessel, (partially exhausted of air,) by unwinding a scroll of dried paper from a reel, and con-

ducting it through heated size; then, after pressing out the superfluous size, winding the paper on to another reel.

A longitudinal section of the apparatus employed for this purpose, is represented in *fig.* 1049. *a*, is the air-tight vessel; *b*, the reel upon which the paper to be sized is wound, from whence it proceeds beneath the guide-roller *c*, and through the heated size, to another guide-roller *d*; it then ascends between the press-rolls *e, f*, (by the revolution of which the paper is drawn from the reel *b* (and is wound upon the reel *g*). A float *h*, is suspended from the cross-bar *i*, of the vessel *a*, for the purpose of diminishing the surface of size exposed to evaporation; and beneath the bottom of the vessel is an enclosed space *j*, into which steam or hot water is introduced, for raising the temperature of the size.

Water-marks.—In the manufacture of all hand-made papers, for the purpose of writing or printing upon, and of much machine-made paper, for the like purposes, it is the practice to form therein a device, name, and date, or some of them, known as the water-mark. These marks are produced by attaching to the surface of the mould or dandy roller, employed in the manufacture of paper (usually by sewing with fine wire), cylindrical and sometimes flattened wire, previously formed into the designs or marks intended to be produced in the paper; which designs or marks, thus attached to and lying above the general surface of the mould, occupy a space thereon, which, if they had been absent, would have been charged with pulp, and thereby cause the sheet of paper in progress of manufacture to be thinner at the particular parts of the mould where the marks or designs are attached, by the thickness of the wire used in the same marks or designs; and the same apparent effect is indeed produced upon the sheet of paper in progress of manufacture as is produced by an ordinary die on any substance it may be caused to act upon,—with this difference, however, that on the sheet of paper the impression is the sunken one.

It is obvious, from the use of cylindrical wire, or flattened wire, having its sides parallel with each other, that the mark ultimately produced will be formed of a number of lines of equal breadth; unless, indeed, in the same figure, wires of different gauges, thicknesses, or breadths, be employed; and even in the latter case (which, indeed, in practice, it is believed seldom occurs), the transition from the different gauges would be abrupt and ill adapted to the proposed end. Also in forming designs of intricacy with wire, a frequent crossing of it is necessary; by which means, at the points of crossing, the mark will necessarily be the thickness of two wires, and, consequently, the water-mark on the sheet of paper will be stronger at those points; or, if to avoid the crossing the wire be cut, so that an end might abut against the length of the wire in an intricate design, the pieces of wire would be so short and so numerous as to render the sewing or fastening of them to the mould exceedingly difficult and of great expense, and, in some cases, wholly impracticable. With respect to the imitation of hand-writing, or the introduction of fac-simile autographs as water-marks, it is scarcely necessary to observe, that the observations before made, in relation to general designs, will apply with greater force to them; and that, at the best, they would be very imperfect, and in many cases, could not be effected at all. The remarks made, with reference to the water-marking upon moulds, is equally applicable to dandy-rollers.

The object of this invention is to remedy the defects before pointed out, and to produce a simple mark, or one of the highest ornamental character or intricacy; the lines of which may vary from a thin line or faint shade to one of a greater depth of tone or breadth; or, on the contrary, from a depth of shade to a fainter one; and also to afford facility for introducing water-marks of the greatest intricacy, without the inconvenience or expense, before alluded to, of crossing the wire, and thus rendering some parts thicker than the main body of the mark, or cutting the wire into innumerable small pieces.

These effects are attained by the following means, whereby also the patentee is enabled to produce fac-similes of ordinary hand-writing and of autograph signatures:—A plate of brass, copper, or other metal, being provided, of the requisite substance to produce the depth of water-mark impression in the pulp (which substance must be determined according to the required weight or thickness of the paper)—to one side of this plate is to be attached, by glue or other suitable means, a piece of card-board or veneer of wood, for the purpose of giving it rigidity and support; and the design to be produced in the pulp as a water mark, having been drawn on paper, is then to be affixed, by glue or other suitable means, to the other surface of the plate. If the sheets of paper to be manufactured are not required to be very heavy, the plate may be thin; and two thin plates of metal may be attached together, and be operated upon at one time. In this case, the paper, with the draught of the design, may be affixed to the outer surface of one of a pair of plates, previously attached together by glue, or other matter, having a piece of card-board or veneer of wood between them, for the purpose of keeping the two thicknesses of metal in contact, and for giving them rigidity. The

plate, supported as stated, or the pair of plates, connected as described, is or are then to be pierced or perforated round the outlines of the device by a saw, adapted to the purpose (after the method of cutting buhl work), according to the pattern or design drawn as before mentioned. The plate or plates having been so pierced, perforated, or cut to the figure of the device, those portions of the metal intended to form the device or water-mark are then to be disengaged from the parts of the plate or plates not required: which having been done, the drawn paper device, card-board, or veneer, must be removed; and if two plates of metal have been cut at one operation, they are to be separated from each other: this separation, as well as the removal of the drawn paper device, card-board, or veneer, can be effected by soaking in hot water or other suitable means. The designs or patterns, thus produced, are now to be attached to the surface of the mould or dandy-roller employed by the paper-maker: which may be done either by sewing with wire, as in the ordinary method of attaching water-marks to moulds or dandy-rollers, or by solder.

In cases where a high finish to the water-mark or design is required or desirable, the edges, and such other parts of the metal as may be desired, should be chamfered off, rounded, or cut down. In order to do this, the metal devices or parts of the plate or plates are to be affixed, by some sufficient means, to a rigid block, to hold them whilst operating upon: the method which the patentee has adopted, is to glue the cut metal device to a flat slab of marble, somewhat larger than the device; and this admits of its being readily removed by soaking in hot water, after the operation, next described, has been performed. The pattern or metal device being thus affixed, the upper surface thereof is then to be dressed by cutting or filing at the parts where it may be necessary, to improve the effect of the pattern; and the edges which have been left sharp by the saw can be removed or rounded by the scorpor or engraver's tool, and then finished off by stoning or other suitable means. The above method of finishing the marks or designs applies only where the device is to be sewn on to the mould or dandy-roller with wire; but when solder is used, the metal device may—after having been cut, as before mentioned, and cleared from the other parts of the cut plate, card-board, or veneer—be at once affixed by solder to the mould or dandy-roller; and the dressing may be then effected by the scorpor or engraver's tool, and the subsequent operation of stoning be performed, as before mentioned.

The patentee, Mr. R. O. Bancks, claims as his improvement or improvements in the manufacture of paper, the adaptation of marks or devices, pierced or cut from plates of metal, or other suitable substance, by saws or other instruments, as described, to the moulds or dandy-rollers used in the manufacture of paper, for the purpose of producing water-marks therein.

Messrs. Amos and Clare have obtained a patent for employing in place of the upper couch roll (for working against the upper surface of the paper), a hollow roll, perforated on its surface, having a section box within it, acted upon by an air-pump, whereby the deposition of colouring matter is rendered equal on both sides of the paper, instead of being greater on the lower side, by the natural subsidence of the colouring matter from the water. They have also specified an improved knitter or pulp strainer, and various other improvements on the ordinary paper machines.—See *Newton's Journal*, xxxvii. 7.

PAPER PULP-METER. Patented by Charles Cowan, Valley-field, near Edinburgh. The object of this apparatus is to measure out a uniform and exact supply of pulp to the paper machine, according to any width and thickness of the web of paper which it may be desired to make. The pulp, after having been prepared in the engines, and mixed in ascertained proportions of raw materials and water, is kept in the pulp or stuff chest. The cup of the pulp-meter which is driven in connection with the paper machine is made to dip into a box, which by means of a ball-cock or valve is always kept full of pulp from the pulp-chest and lifts, and delivers the requisite quantity of pulp to make the width and thickness of the web required. This is done by means of the slide upon the cup, which can be set even while the apparatus is in motion, so as to deliver the number of cubical inches of pulp at each dip required for the particular paper to be made, which can be ascertained by a very simple calculation. In this way uniformity of thickness in every sheet of paper manufactured is readily obtained.

PAPER AND PRINTING. (*Exhibition.*) Paper of every description, printing and bookbinding, with the miscellaneous articles connected with correspondence, and useful and ornamental stationery, form the subject of the present class. The manufacture of these articles, ministering not to the personal or domestic wants of mankind, so much as to their intellectual requirements, is one the annual increase of which is coextensive with the diffusion of knowledge. And it may be truly said, that, morally and intellectually considered, the present class relates to a species of industry exercising indirectly a more extensive influence over social economy than any of those into which the exhibition has been subdivided. Books, it has been said, carry the productions of the human mind

over the whole world, and may be truly called the raw materials of every kind of science and art and of all social improvement. The sub-classes are as follows:—A. paper, in the raw state as it leaves the mill, such as brown paper, millboards, printing, writing, and drawing papers, &c.; B. articles of stationery, as envelopes, lace papers, fancy papers, ornamental and glazed papers, sealing wax, wafers, inks of all kinds, &c.; C. pasteboards, cards, &c.; D. paper and scaleboard boxes, cartonnerie, &c.; E. printing, not including printing as a fine art, and printing inks and varnishes; book-binding in cloth, velvet, vellum, &c.; fancy books, portfolios, desks, &c.

The localities from whence the articles exhibited have been sent are much less restricted than in preceding classes. Many of the exhibitors appear in the capacity of producers of small articles for fancy purposes; and as these are obviously capable of being made at home, requiring taste and minute skill rather than mechanical power for their manufacture, the places from which they have been forwarded for exhibition have not the special interest attaching to great producing towns or cities, where thousands of mechanics and operatives are all occupied in one department of manufacture. From the metropolis, however, where a large demand for such articles exists, the great proportion of them are derived. London also represents most largely the enormous printing resources of this country. But of these, as specimens only of single works can appear, but a faint idea can be gained from the examples exhibited. In one of the greatest establishments of the metropolis, twenty machines are constantly occupied, each of which is capable of throwing off from 3,000 to 4,000 impressions per hour, and in addition a large number of printing machines for fine work are employed. These great printing establishments resemble very closely the large manufactories of other districts, only their organization differs with the peculiar nature of the manufacture, if the mechanical production of printed books may be so termed.

Paper, more legitimately reckoned among manufactures than printing, has a certain limitation to districts for particular kinds. Considerably more is made in England than in Scotland or Ireland. Kent is celebrated for its fine writing and drawing papers. From Lancashire, Berkshire, Hertford, and Derbyshire, papers of various kinds are supplied. The quantity of paper annually manufactured in England two years ago amounted to 132,132,657 lbs.; in 1834, it was a little more than half that quantity. In 1839 it was estimated that the quantity used, if equally divided among the population, would have been about three pounds and three quarters for each individual.

A variety of mechanical improvements, both in the production of paper and in that of printed books, has been introduced of late. In the manufacture of paper, the substitution of machine for hand labour, has been attended with the most momentous results. In 1801, the price of a ream of paper of a particular description was 36s.; in 1843 the same paper could be purchased for rather less than half this sum. In 1721 it is estimated that 300,000 reams of paper were annually produced in Great Britain. In 1841 97,105,550 lbs. were made in the United Kingdom the total annual value is at present not far short of two millions sterling. Much of the increase thus exhibited is due to the introduction of mechanical power; but the fiscal regulations upon this branch of industry, which were formerly extremely oppressive, having been removed to some extent, another cause of increased production and consumption is thus super-added. Paper may, however, be likewise regarded as a chemical product, as it is certain that a large amount of chemical knowledge has been successfully combined with mechanical skill in its preparation.

By the co-operative forces of chemical processes and mechanical instruments, the most refuse matter becomes converted into a white and pure material. As an evidence of the enormous length of paper produced by mechanical power two great rolls are exhibited; one is 750 yards long, the other 2,500 yards in length.

The application of improved machinery to printing is also of recent date, and has been attended with results of great moment. Progress is still made in this direction: an entirely new principle in printing (the vertical) has been introduced, the application of which for the rapid multiplication of newspapers is extending. By this arrangement (the vertical), the power of production is only limited by the size of the machine.

Among many interesting specimens of typography, those which exhibit the production of books in other tongues, by type cast in England, will attract notice. The Holy Scriptures are exhibited in one hundred and fifty different languages,—a noble evidence of the highest application of industry to the enlightenment and welfare of mankind. Beautiful specimens of the bookbinder's art are likewise shown.

An envelope-folding machine, placed at the side of the Main Avenue, is a striking instance of the successful application of mechanical movements to the performance of the most delicate and complicated actions. By this machine, the movements of the hand of the folder are not only exactly imitated, but the result is more accurate and certain, and the power of production is very largely increased.

The peculiar interest which attaches to the objects in this class, as the most powerful agents in the social and intellectual improvement of man, cannot fail to be awakened by the most casual inspection. Papers, printing, and bookbinding, are, however, only the raw material, the application and reproduction of which is dependent upon the powers of the mind, not on those of matter.

10. *Fisher, Jabez Henry, New North Road, Hoxton, Inventor.*—Specimen of a bank-note for the prevention of forgery, printed in a chemical watercolour, from a steel plate engraving, the process producing two colours at one operation; the lettering in black, and the ornamental background in a neutral tint. Any signature upon this note cannot be erased without changing the colour. The letterpress on the note cannot be transferred or copied, and is printed on a prepared paper.

23. *Kirby, John, 103 Cornwall Road, Lambeth, Producer.*—Specimens of split paper and improved method of mounting woodcuts, for illustrating books, framing, and other purposes, and for their better preservation.

The method of splitting paper of the thinnest texture is extremely simple. Two pieces of calico are firmly cemented on the sides of the paper and dried. By a gentle pull on each side, the paper splits into halves, one of which adheres to the calico on one side, and the other to its opposite, the adhesion between the paper and the calico being greater than that of the surfaces of the paper to each other. The split portions may then be removed by damping, and so loosening the paste between the calico and paper. A bank-note, although of extremely thin texture, can in this way be separated into two halves, on one of which remains the impression of the plate, while the other is blank.

In the interesting collection of paper in the Exhibition from various paper mills, there are groups whose degrees of excellence must be estimated by very different standards; as, for instance, the brown wrapping and the fine hand-made drawing papers, the sugar and the fine printing papers, the bibulous plate-paper for engravers' use, and the hard sized writing papers. Collectively, it exhibits at one view the various qualities which are sought for by English consumers, and which in many respects differ from those required by our Continental neighbours; as an example, may be quoted the substantial English writing-papers and the thin post papers of France and Belgium, whose different qualities arise from the difference of postal regulations in those countries.

The system of producing paper in continuous lengths of machinery was first introduced by Messrs. Fourdrinier into this country, they having purchased the patent right of Mr. Gamble, who in 1804, obtained permission from the French government to bring to England a model of a machine invented in 1799 by Louis Robert, who was then employed in the paper works of Essonne. This machine of Mr. Robert was essentially imperfect, but it was brought to a state of perfection for Messrs. Fourdrinier by the ingenuity of Mr. Bryan Donkin: upon this has been founded the various descriptions of paper-making machines which have since that time been introduced. They consist essentially of contrivances by which the paper pulp is made to flow on the surface of an endless wire web; a rapid up and down motion being given to it for the purpose of shaking the water out of the pulp, and thus producing a complete interweaving of the textile filaments. The continuous roll of paper thus formed is turned off upon a second solid cylinder covered with felt, upon which it is condensed by a third, and eventually delivered to drying rollers.—*Exhibition, Report of.*

Swedish filtering paper is made with pure water, and is more free from impurity than any other; this is, in fact, pure cellulose, and yields only half a per cent. of ash on incineration.

Laid papers are those with a ribbed surface; wove papers those with a uniform surface. Blue papers under the microscope no longer appear of uniform tint; on the contrary, the particles of colour are seen widely separated.

In reference to the pulp in its various stages of preparation, it may be stated that numerous attempts have been made to employ other fibres besides those of cotton and flax, in the manufacture of paper; for instance, straw, hop-vine, grasses, refuse of sugar cane, wood shavings, &c.; and, although paper has been produced from these materials, yet, commercially, the attempts have been unsuccessful.

76. *De la Rue, Thomas, & Co., 110 Bunhill Row, Manufacturers and Proprietors.* *Envelope-folding machine invented by Edwin Hill and Warren De la Rue.*—The following is the action of this machine:—The feeding-boy places the previously cut blank envelopes on to a small platform, which rises and falls in the rectangular recess formed by the cylindrical axes of the folders, the bearings of the folders serving by their elongation to guide the envelope into its place at the moment of the small platform falling. A plunger now descends and creases the envelope by carrying it between the folder-axes, at the same time turning the flaps upwards in a vertical direction. The plunger, which descends as a whole, now divides into two parts, the ends rising and the sides

remaining down to hold the envelope until the end-folders have operated; these latter turn over the flaps, the one on the right of the feeding-lad taking a slight precedence, and being closely followed by the gumming apparatus, which takes gum from an endless blanket working in a trough, and, after applying it to the two end flaps, retires, at the same time the remaining half of the plunger moves upwards, to allow of the side folders turning over the remaining two flaps, and the folder nearest the feeder taking precedence. During these operations, the end folders have remained at rest, and the whole four open simultaneously. The taking-off apparatus with its fingers tipped with vulcanized caoutchouc, now moves forward over the folded envelope, which is lifted upwards by the rise of the small platform and retreats with it, placing each envelope, as it is successively folded, under those which have preceded it. The envelopes are now knocked over on to an endless blanket, and are conducted by it between two cylinders for a final squeeze, and then rise in a pile up the trough. There is a provision in the machine by which the gummer is prevented placing gum upon the platform, in case the feeder omits feeding in an envelope. This machine works at the rate of 2,700 envelopes per hour, and although superseding hand-labour in folding, it is satisfactory to find that, instead of displacing hands, its introduction, by extending the consumption, has in reality created work for more than it has displaced.

Although the fashion of using envelopes was common in France, and had been, to a small extent, introduced into England prior to 1839, yet their consumption was too insignificant to call forth any but the rudest mechanical appliances. It is to the stimulus created by the adoption, in 1839, of Mr. Rowland Hill's system of postage reform, and the consequent increased demand for envelopes, that their manufacture owes its rank among the arts, and its possession of some of the most ingenious machinery recently invented.

The total annual number of letters passing through the Post Office in the United Kingdom before the change in the postage was about 76,000,000. The fourpenny rate and the alteration in the system of charge by number of enclosures to that by weight, was introduced on the 5th of December, 1839, and on the 10th of January, 1840, the rate was reduced to one penny; during that year the number of letters increased to 169,000,000, about half of which were enclosed in envelopes. The number of letters has been steadily increasing since that period, and during the year 1850, it reached the astonishing number of 347,000,000, or 1,000,000 per day; the proportion of letters enclosed in envelopes has likewise increased from one-half to five-sixths of the total quantity, so that in round numbers 300,000,000 of envelopes pass annually through the Post-Office; besides which there is nearly an equal number used in private conveyance. What does this million of envelopes contain? Their exposition would furnish an instructive and entertaining study.

In illustration of the articles sometimes sent by post, it may be cited, that some years back, Professor Henslow was in the habit of receiving from members of an agricultural society which he had established, specimens of living slugs of various kinds, sent for examination, with a view to his advice for their extermination. Were it not for the cheap postage, many of the publishing societies now in existence would not have been established, on account of the expense of collecting manuscripts, transmitting proofs, and circulating books. But it is not only in this way that the postal reform has extended its benefits, for with the reduction of rates, a liberal policy has increased the facilities of delivery by the establishment since 1839 of 4,600 new post offices, which are estimated as serving about 14,000 villages.

154. *Specimens of Books and Tracts of the Religious Tract Society*, instituted 1799. Depositories, 56. Paternoster Row, 65. St. Paul's Churchyard, and 164. Piccadilly. Treasurer, John Gurney Hoare, Esq.; Honorary Secretaries, Rev. W. W. Champneys, M.A., and Rev. Ebenezer Henderson, D.D.; Corresponding Secretary, Mr. Jones.

The Society was formed to promote the circulation of religious books and treatises in foreign countries, as well as throughout the British dominions. It constitutes a Christian union of members of the Established Church and of Protestant dissenters. It has printed important tracts and books in about 100 languages; its annual circulation from the depository in London, and from various foreign auxiliaries, amounts to about 24,000,000; its receipts for sales and benevolent objects, to more than 62,000*l.*; and its total distribution to March, 1851, including the issues of its affiliated societies, to about 549,000,000 copies of its publications. There are now about 4,743 English publications, besides several hundred in foreign languages, on its catalogue. These works are varied in size and contents, and suited to different classes of the community. Several books and tracts specially designed to improve and commemorate the Great Exhibition have been issued in English, French, German and Italian. By a carefully arranged system in the concerns of the depository, the sale of the publications is made to cover all the expenses of producing them, and of the necessary establishment of the Society.

Thus, the whole of the subscriptions, donations and contributions is applied to the gratuitous circulation of its publications, without any deduction or charge whatever. In aid of home and foreign benevolent objects the Society receives about 5,560*l.*, per annum, while its grants during the past year were 8,560*l.*, being 2,000*l.* beyond the receipts. The committee have supplied 3,028 libraries at half price to national, British, parochial, day, and Sunday schools, which were unable to pay the full amount.

The total grants of libraries for various interesting objects amount to 6,055.

The Society has translated, printed, and circulated works in the following languages:

Northern Europe.—Icelandic, Swedish, Lapponese, Finnish, Danish, Norwegian.

Southern Europe.—French, German, Latin, Romanese, Enghadin, Italian, Maltese, Modern Greek, Albanian, Turkish, Turkish in Greek character, Turkish in Armenian character, Moldavian, Bulgarian, Syriac.

China and Indo-Chinese Countries.—Chinese, Assamese, Shyam, Nagas, Burmese, Peguan, Talung, Karen, Siamese, Laos, Cambodian, Cochinchinese, Loo-Choon, Japanese, Korean, &c.

Through the disinterested agency of devoted friends and missionaries of different denominations, several languages have, for the first time, been brought into a written form, and a sacred character has been given by the Christian press to the earliest literature of a people just emerging from a state of barbarism. As an illustration of the extent of the Society's operations, it may be stated that Bunyan's celebrated work, "The Pilgrim's Progress," has been issued in 28 of the principal languages of the earth, spoken probably by more than one-half of the human family. In some instances the work has been printed in Roman characters, as in the following example:—

In Tahiti, for the inhabitants of various islands in the Pacific Ocean, thus:—

I to'u hahae re a na roto i medebara o teie nei ao, haeri atura van i te hoe vahi, e ana tei taua vahi ra, tapae atura van i reira e rohia ihora i te taoto i roto i taua ana ra.

The original of this translation is the following:—

As I walked through the wilderness of this world, I lighted on a certain place where was a den, and laid me down in that place to sleep, and as I slept I dreamed a dream.

171. *Gall, James, Myrtle Bank, Edinburgh, Inventor.*—Gall's triangular alphabet for the blind, which by its similarity to the common Roman alphabet is easily read by the eye, and may be taught without previous instruction. This alphabet is considered as an improvement on circular alphabets, by its angular form; the letters are rendered more distinct to the touch; and by the exclusion of the capitals, the attention of the blind is concentrated upon 26 instead of 52 letters, and the size of the printing may be reduced. Volume, containing the Epistle to the Ephesians, printed for the blind in Gall's triangular alphabet with letters serrated.

Gall's apparatus for writing by and to the blind.—The blind can by this invention readily correspond by post, and can keep books and other memoranda. The apparatus consists of a stuffed frame on which the paper is placed; of a cover with bars to guide the lines, which are written from the bottom upwards; and of small stamps, with the letters formed of common pins, which are pricked through the paper, and read on the opposite side. By means of the two register points on each side of the frame, and by shifting the cover one half line up, the paper is written on both sides, each perfectly legible either by the fingers or the eye.

174. *Muir, Robert, 4, Dunlop Street, Glasgow, Inventor.* Electro-stereotype plate for letter-press printing. This specimen is from a mould of gutta percha, taken from a page of diamond types in a screw press. The gutta percha was laid on warm, the pressure applied immediately, and left on for fifteen minutes. When the mould was taken off, it was brushed over with plumbago, and copper deposited upon it by the known process. When the copper deposit is backed up with gutta percha, it is ready for press.

The advantage of electro-stereotype over stereotype is that it will last much longer, and work much cleaner. The exhibitor has worked one of each together, and when the stereotype was completely worn, the electro-stereotype was as good as at first.

Gutta percha plate to be used in letter-press printing. Plates made of gutta percha from woodcuts, will work a large impression with letter-press; advantageous when woodcuts are expensive, as the originals might be saved. Gutta percha plates can be made in a short time at a trifling cost; and when 2, 4, or 6, are worked together, it will greatly facilitate the work, and lessen expense.

Make a mould from a woodcut by the method above described; brush it over with plumbago; lay it on the press, face up, and put warm gutta percha into it; apply the pressure as before. Several plates may be got from the same mould.

This process appears to offer many advantages, if the practical difficulties of completely

covering the impressions of the type letters, or the lines of an engraving, with plumbago are not too great. The gutta percha plate, being properly prepared, is connected with the voltaic battery, and placed in a solution of the sulphate of copper, which, when undergoing electro-chemical decomposition, deposits pure copper in all the lines and over the entire surface. It would appear, if lead was used instead of gutta percha for backing the plate, that it would be better fitted for printing than when gutta percha is employed.

175. *Wyld, James, Charing Cross, East, 454, West Strand, 2, Royal Exchange, and the Great Globe, Leicester Square,—Producer.* An Atlas of the World, comprehending 52 separate maps of its various countries, constructed and drawn from the latest astronomical and geographical observations. Imperial quarto, coloured and handsomely half-bound.

Popular Atlas, containing 48 maps of the various parts of the globe, with letter-press description to accompany each map.

The World on Mercator's projection. A new map containing the most recent geographical information, and constructed on a new principle; 4 large sheets. The World on Mercator's projection, colored; one large sheet.

Post Roads of Germany and the adjacent states, with the posts marked. The railroads, the sea-packet routes, and the internal steam navigation. Two sheets in cases. The British Isles, with the topographical and physical features; the lines of railway, their primary and intermediate stations; the land and water communications of the counties, and the steam-packet routes, with the distances from port to port. Compiled from the Ordnance Survey; 2 sheets.

England, Wales, and the greater part of Scotland, a railway and topographical map, drawn from the triangulation of the Ordnance Survey, and the surveys of the railway companies and other sources of information, showing the lines of railways, the inland navigation, the great and cross roads, market towns, and villages, with the physical features. 4 sheets.

Plans of London and Westminster, with the Borough of Southwark, including the adjacent suburbs, with all the additions and improvements to the present time, reduced from the large survey, with an alphabetical list of the principal streets, squares, public buildings, &c., and reference to their situation on the plan; also a statistical table of population, &c. 2 sheets.

Map of the country 25 miles round London, upon a scale of 1 inch to the mile, showing the turnpike and cross roads, railroads, and stations, rivers, woods, commons, seats of the nobility and gentry, as well as the market towns, villages, &c. 4 sheets.

201. *British and Foreign Bible Society, Earl Street, Blackfriar,—Producer.* Specimens, consisting of 165 books in different languages, from 170 versions of the Holy Scriptures, either in whole or in part, which have been published, directly or indirectly, by the Society, of which 118 are from translations never before printed; and of which more than twenty-four millions of copies have been circulated since its institution in 1804.

Eight specimens of four editions of the English Bible, showing the improvement made between the years 1816 and 1851, in reference to quality of paper, printing and binding, at an average reduction of 62 per cent. in the cost price.

PARAFFINE. Distil beech-tar to dryness, rectify the heavy oil which collects at the bottom of the receiver, and when a thick matter begins to rise, set aside what is distilled, and urge the heat moderately as long as any thing more distils. Pyrène passes over, containing crystalline scales of paraffine. This mixture being digested with its own volume of alcohol of 0.833, forms a limpid solution, which is to be gradually diluted with more alcohol, till its bulk becomes 6 or 8 times greater. The alcohol, which at first dissolves the whole, lets the paraffine gradually fall. The precipitate being washed with cold alcohol till it becomes nearly colorless, and then dissolved in boiling alcohol, is deposited on cooling in minute spangles and needles of pure paraffine.

Or the above mixture may be mixed with from $\frac{1}{4}$ to $\frac{1}{2}$ its weight of concentrated sulphuric acid, and subjected for 12 hours to digestion, at a heat of 150° F., till, on cooling, crystals of paraffine appear upon the surface. These are to be washed with water, dissolved in hot alcohol, and crystallized. Paraffine is a white substance, void of taste and smell, feels soft between the fingers, has a specific gravity of 0.87, melts at 112° Fahr., boils at a higher temperature with the exhalation of white fumes, is not decomposed by dry distillation, burns with a clear white flame without smoke or residuum, does not stain paper, and consists of 85.22 carbon, and 14.78 hydrogen; having the same composition as olefiant gas. It is decomposed neither by chlorine, strong acids, alkalis, nor potassium; and unites by fusion with sulphur, phosphorus, wax, and rosin. It dissolves readily in warm fat oils, in cold essential oils, in ether, but sparingly in boiling absolute alcohol. Paraffine is a singular solid bicarburet of hydrogen; it has not hitherto been applied to any use, but it would form admirable candles.

The interesting researches of Reichenback, above briefly detailed, have lately begun to assume a more practical aspect in consequence of the efforts made by several companies in this country to work up or utilise the peat bogs of Ireland. The progress yet made in this patriotic endeavour has not been such as to hold-out any great hope, either that the project will pay in a commercial sense, or that the peat of Ireland can be utilised at anything short of a great national sacrifice. In fact, all the money hitherto invested in these peat projects has been as completely lost to its owners as if it had not only really, but literally, been thrown into a bog. Part of this unsatisfactory result is no doubt owing to the newness of the undertaking, to the want of practical knowledge, and to the purely visionary and unfounded calculations of the projectors, who have rushed at conclusions in unison rather with their wild hopes than with the sober deductions of scientific experience, and without any solid data upon which to found their egregious assertions, have made "the wish father to the thought," and declared that to be a fact which had scarcely the consistence of a vague probability. As the subject is one essentially contained within the realms of manufacturing chemistry, we deem it requisite to give a general view of these peat schemes, but without entering into a specific examination of any one project. By one class of schemes, the solid or fixed residue of the peat is chiefly contemplated, by another the fluid and gaseous or volatile products are sought for, whilst a third class unites both fixed and volatile products, and may therefore be said to comprehend the whole question. The first includes the makers of peat charcoal *per se*; the two last come more immediately within the scope of our observations, and although these have hitherto failed to elucidate the principles upon which the manufacture of peat into saleable products depends, they have nevertheless brought forth an abundance of evidence, that more is to be done in this way than was previously anticipated by scientific men. When peat is subjected to distillation at a red heat, it evolves matters precisely similar to those given off by wood and some kinds of bitumen, that is to say, tar, acetic acid, pyroligneous spirit, ammonia, and gas; these substances, though constant in their presence, are, however, extremely variable in their quantities, owing to the degree of heat which has been employed for their production. Thus, if a very high temperature be employed, little else than gas is produced, whereas with a very low and dull red heat the quantity of tar is prodigiously increased. The latter is therefore the temperature most to be desired, but as this low heat necessitates a very slow and long continued process, the common practice is to steer a middle course, between loss from destruction of products on the one hand, and cost from slowness of production on the other. In the case of wood distillation, where the profit is chiefly looked for from acetic acid, this middle course is unquestionably correct, and guiding themselves by this description of experience the distillers of peat have resorted to the same method. Indeed, they have even sought by an increased temperature to quicken their operations, and compensate by this means for the comparative poverty of the article they had to employ, since peat is not nearly so rich in valuable products as wood is. But this had given rise to a great and fatal error, which nothing but a want of perception as regards the differences of the two cases could for one moment have permitted. With wood it is, as we have said, acetic acid which forms the chief item of value; with peat the acetic acid is not worth collecting; with wood the paraffine is a mere bagatelle, whereas with peat the paraffine must be regarded as the mainstay of the manufacture, and without which the peat of Ireland will remain as it is, until that seemingly remote period of future history, when the arts and manufactures shall have reached in that country a degree of perfection akin to what now prevails throughout Great Britain. To make charcoal, or to make any bulky article of merchandise in Ireland, is mere folly at present, for as it cannot be used on the spot, and must come to England for consumption, the cost of transit shuts it out of every market. Therefore a compact valuable substance like paraffine is precisely the kind of goods into which Irish peat may be turned with a fair prospect of remuneration, for were it not for the expense of carriage, the peat itself might be sent to market. In the manufacture of peat-products every effort ought therefore to have been directed to the increase of this article. All else might and ought to have been held subsidiary to this one point, and more especially so as the very means which serve to insure a large formation of paraffine have the same effect upon the production of the pyroligneous spirit, which is the only other article that peat yields of a quality to pay the cost of transit.

But no well directed efforts have hitherto been applied in this direction, and the utmost amount of paraffine and pyroligneous spirit obtained by any one of the peat companies now struggling for existence in Ireland has been only at the rate of three pounds weight of paraffine and half a gallon by measure of pyroligneous spirit from one ton of peat. True, indeed, several gallons of very fetid and worthless oil have also resulted, but these add nothing to the profit of the undertaking. As it is very clear that the working of peat at present can never pay unless some very important modifications are introduced into the existing processes,

we shall here briefly describe the conditions upon which alone success can be hoped for, and leave it to those interested in the practical application of our remarks, to carry the principles out in detail. If either paraffine or pyroligneous spirit be passed in a state of vapour through a red-hot iron or porcelain tube, it will be seen that both of these substances are decomposed and destroyed: from the former a quantity of gas, foetid oil, and charcoal results, from the latter, gas and a minute quantity of volatile oil alone arise. In both cases, however, the material operated upon is destroyed by the heat, and resolved into worthless products, and this is the only observation which need be made in connexion with such an experiment, for it demonstrates most conclusively that in the distillation of peat as now practised, nearly the whole of the paraffine and pyroligneous spirit must be destroyed, except the small quantity mechanically protected from the heat, and carried forward to the condenser by the gaseous products simultaneously evolved with it. It is, we say, obvious that the 3 lbs. of paraffine now procured from 1 ton of peat, must have been mechanically carried out of the red-hot furnace or retort too rapidly for the destroying agency of the heat to have acted upon it, and but for this action of the gas, no paraffine whatever would be obtained, and the same remark applies to the pyroligneous spirit. Such being the case, it appears to us that the gas given off by peat is not, under any circumstances, very large, this ought to be reconducted over fresh peat in the act of distillation, by which the nascent paraffine and pyroligneous spirit will be rapidly swept out of the retort, and carried away from the injurious effect of the heat into the condenser, whence they may be securely taken. It cannot be necessary that we should enter into a detail of the arrangements requisite for completing the idea here developed; the principle is substantially explained above, and nothing can be simpler than to devise the mechanical construction of retorts adapted for such a purpose. Either a system of reciprocation between one retort and another, or between two separate beds of retorts, or the collection and subsequent use of the gas into and from a holder, might be put in practice. The main feature would still continue, and depend upon the same circumstance, viz, the restricted agency of the heat upon the recently volatilized products of the peat.

In this way there can be no doubt that much of the paraffine now resolved into worthless gas may be turned into the market in a solid form, and if even the increased production of this article extended no farther than from 3 lbs. to 10 lbs. from every ton of peat, yet this alone would be sufficient to resuscitate the hopes of commercial men, and convert the bogs of Ireland into firm and substantial materials for the investment of British capital and enterprise,—“a consummation most devoutly to be wished.”—*Mr. Lewis Thompson.*

PARCHMENT. (*Parchemin, Fr.; Pergament, Germ.*) This writing material has been known since the earliest times, but is now made in a very superior manner to what it was anciently, as we may judge by inspection of the old vellum and parchment manuscripts. The art of making parchment consists in certain manipulations necessary to prepare the skins of animals of such thinness, flexibility, and firmness, as may be required for the different uses to which this substance is applied. Though the skins of all animals might be converted into writing materials, only those of the sheep or the she-goat are used for parchment; those of calves, kids, and dead-born lambs for vellum; those of the he-goat, she-goat, and wolves for drum-heads; and those of the ass for battle-doors. All these skins are prepared in the same way, with slight variations, which need no particular detail.

They are first of all prepared by the leather-dresser. After they are taken out of the lime-pit, shaved, and well washed, they must be set to dry in such a way as to prevent their puckering, and to render them easily worked. The small manufacturers make use of hoops for this purpose, but the greater employ a *herse*, or stout wooden frame. This is formed of two uprights and two cross-bars solidly joined together by tenons and mortises, so as to form a strong piece of carpentry, which is to be fixed up against a wall. These four bars are perforated all over with a series of holes, of such dimensions as to receive slightly tapered box-wood pins, truly turned, or even iron bolts. Each of these pins is transpierced with a hole like the pin of a violin, by means of which the strings employed in stretching the skin may be tightened. Above the *herse*, a shelf is placed, for receiving the tools which the workman needs to have always at hand. In order to stretch the skin upon the frame, larger or smaller skewers are employed, according as a greater or smaller piece of it is to be laid hold of. Six holes are made in a straight line to receive the larger, and four to receive the smaller skewers or pins. These small slits are made with a tool like a carpenter's chisel, and of the exact size to admit the skewer. The string round the skewer is affixed to one of the bolts in the frame, which are turned round by means of a key, like that by which pianos and harps are tuned. The skewer is threaded through the skin in a state of tension.

Every thing being thus prepared, and the skin being well softened, the workman

stretches it powerfully by means of the skewers; he attaches the cords to the skewers, and fixes their ends to the iron pegs or pins. He then stretches the skin, first with his hand applied to the pins, and afterwards with the key. Great care must be taken that no wrinkles are formed. The skin is usually stretched more in length than in breadth, from the custom of the trade; though extension in breadth would be preferable, in order to reduce the thickness of the part opposite the backbone.

The workman now takes the fleshing tool represented under CURRYING. It is a semi-circular double-edged knife, made fast into a double wooden handle. Other forms of the fleshing-knife edge are also used. They are sharpened by a steel. The workman seizes the tool in his two hands, so as to place the edge perpendicularly to the skin, and pressing it carefully from above downwards, removes the fleshy excrescences, and lays them aside for making glue. He now turns round the *herse* upon the wall, in order to get access to the outside of the skin, and to scrape it with the tool inverted, so as to run no risk of cutting the epidermis. He thus removes any adhering filth, and squeezes out some water. The skin must next be ground. For this purpose it is sprinkled upon the fleshy side with sifted chalk or slaked lime, and then rubbed in all directions with a piece of pumice-stone, 4 or 5 inches in area, previously flattened upon a sandstone. The lime gets soon moist from the water contained in the skin. The pumice-stone is then rubbed over the other side of the skin, but without chalk or lime. This operation is necessary only for the best parchment or vellum. The skin is now allowed to dry upon the frame; being carefully protected from sunshine, and from frost. In the arid weather of summer a moist cloth needs to be applied to it from time to time, to prevent its drying too suddenly; immediately after which the skewers require to be tightened.

When it is perfectly dry, the white color is to be removed by rubbing it with the woolly side of a lambskin. But great care must be taken not to fray the surface; a circumstance of which some manufacturers are so much afraid, as not to use either chalk or lime in the polishing. Should any grease be detected upon it, it must be removed by steeping it in a lime pit for 10 days, then stretching it anew upon the *herse*, after which it is transferred to the *scraper*.

This workman employs here an edge tool of the same shape as the fleshing-knife, but larger and sharper. He mounts the skin upon a frame like the *herse* above described; but he extends it merely with cords, without skewers or pins, and supports it generally upon a piece of raw calfskin, strongly stretched. The tail of the skin being placed towards the bottom of the frame, the workman first pares off, with a sharp knife, any considerable roughnesses, and then scrapes the outside surface obliquely downwards with the proper tools, till it becomes perfectly smooth: the fleshy side needs no such operation, and indeed were both sides scraped, the skin would be apt to become too thin, the only object of the scraper being to equalize its thickness. Whatever irregularities remain, may be removed with a piece of the finest pumice-stone, well flattened beforehand upon a fine sandstone. This process is performed by laying the rough parchment upon an oblong plank of wood, in the form of a stool; the plank being covered with a piece of soft parchment stuffed with wool, to form an elastic cushion for the grinding operation. It is merely the outside surface that requires to be pumiced. The celebrated Strasburgh vellum is prepared with remarkably fine pumice-stones.

If any small holes happen to be made in the parchment, they must be neatly patched, by cutting their edges thin, and pasting on small pieces with gum water.

The skins for drum-heads, sieves, and battledoors are prepared in the same way. For drums, the skins of asses, calves, or wolves are employed; the last being preferred. Ass skins are used for battledoors. For sieves, the skins of calves, she-goats, and, best of all, he-goats are employed. Church books are covered with the dressed skins of pigs.

Parchment is colored only green. The following is the process. In 500 parts of rain water, boil 8 of cream of tartar, and 30 of crystallized verdigris; when this solution is cold, pour into it 4 parts of nitric acid. Moisten the parchment with a brush, and then apply the above liquid evenly over its surface. Lastly, the necessary lustre may be given with white of eggs, or mucilage of gum arabic.

PARTING (*Départ*, Fr.; *Scheidung*, Germ.), is the process by which gold is separated from silver. See ASSAY, GOLD, REFINING, and SILVER.

PASTEL, is the French name of colored crayons.

PASTE, is a dye stuff, allied to INDIGO, which see.

PASTES, or **FACITIOUS GEMS**. (*Pierres précieuses artificielles*, Fr.; *Glaspasten*, Germ.) The general vitreous body called Strass, (from the name of its German inventor,) preferred by Fontanier in his treatise on this subject, and which he styles the Mayence base, is prepared in the following manner:—8 ounces of pure rock-crystal or flint in powder, mixed with 24 ounces of salt of tartar, are to be baked and left to cool. The mixture is to be afterwards poured into a basin of hot water, and treated with dilute nitric acid till it ceases to effervesce; and then the frit is to be washed till the water comes off

tasteless. This is to be dried, and mixed with 12 ounces of fine white-lead, and the mixture is to be levigated and elutriated with a little distilled water. An ounce of calcined borax being added to about 12 ounces of the preceding mixture in a dry state, the whole is to be rubbed together in a porcelain mortar, melted in a clean crucible, and poured out into cold water. This vitreous matter must be dried, and melted a second and a third time, always in a new crucible, and after each melting poured into cold water, as at first, taking care to separate the lead that may be revived. To the third frit, ground to powder, 5 drachms of nitre are to be added; and the mixture being melted for the last time, a mass of crystal will be found in the crucible, of a beautiful lustre. The diamond may be well imitated by this Mayence base. Another very fine white crystal may be obtained, according to M. Fontanier, from 8 ounces of white-lead, 2 ounces of powdered borax, $\frac{1}{2}$ grain of manganese, and 3 ounces of rock-crystal, treated as above.

The colors of artificial gems are obtained from metallic oxydes. The *oriental topaz* is prepared by adding oxyde of antimony to the base; the *amethyst*, by manganese with a little of the purple of Cassius; the *beryl*, by antimony and a very little cobalt; yellow artificial diamond and opal, by horn-silver (chloride of silver); blue-stone or sapphire, by cobalt. The following proportions have been given:—

For the *yellow diamond*. To 1 ounce of strass add 24 grains of chloride of silver, or 10 grains of glass of antimony.

For the *sapphire*. To 24 ounces of strass, add 2 drachms and 26 grains of the oxyde of cobalt.

For the *oriental ruby*. To 16 ounces of strass, add a mixture of 2 drachms and 48 grains of the precipitate of Cassius, the same quantity of peroxide of iron prepared by nitric acid, the same quantity of golden sulphuret of antimony and of manganese calcined with nitre, and 2 ounces of rock crystal. Manganese alone, combined with the base in proper quantity, is said to give a ruby color.

For the *emerald*. To 15 ounces of strass, add 1 drachm of mountain blue (carbonate of copper), and 6 grains of glass of antimony; or, to 1 ounce of base, add 20 grains of glass of antimony, and 3 grains of oxyde of cobalt.

For the *common opal*. To 1 ounce of strass, add 10 grains of horn-silver, 2 grains of calcined magnetic ore, and 26 grains of an absorbent earth (probably chalk-marl) *Fontanier*.

M. Douault-Wieland, in an experimental memoir on the preparation of artificial colored stones, has offered the following instructions, as being more exact than what were published before.

The base of all artificial stones is a colorless glass, which he calls *fondant*, or flux; and he unites it to metallic oxydes, in order to produce the imitations. If it be worked alone on the lapidary's wheel, it counterfeits brilliants and rose diamonds remarkably well.

This base or strass is composed of siliceous matter, potash, borax, oxyde of lead, and sometimes arsenic. The siliceous matter should be perfectly pure; and if obtained from sand, it ought to be calcined and washed, first with dilute muriatic acid, and then with water. The crystal or flint should be made red-hot, quenched in water, and ground, as in the potteries. The potash should be purified from the best pearlash; and the borax should be refined by one or two crystallizations. The oxyde of lead should be absolutely free from tin, for the least portion of this latter metal causes milkiness. Good red-lead is preferable to litharge. The arsenic should also be pure. Hessian crucibles are preferable to those of porcelain, for they are not so apt to crack and run out. Either a pottery or porcelain kiln will answer, and the fusion should be continued 24 hours; for the more tranquil and continuous it is, the denser is the paste, and the greater its beauty. The following four recipes have afforded good strass:—

pattern, may be set up and displayed, the variety of designs it can produce, and the ease and simplicity of accomplishing them. It is not at all necessary to paint the pattern on paper, after viewing it through the mirrors, as the scales attached show at once the required number of threads of each colour, and how many repeats are necessary for the breadth of the web; and it displays at once not only the repeat, but the whole breadth, and a considerable portion of the length of the cloth at one view.

By this invention, the precise effect of a pattern may be produced in the course of a few minutes, without any expense, multiplied to any extent, and it may be enlarged or diminished at pleasure. The chief novelty, however, of this machine, which was exhibited for its simplicity and the ease of its adaptation, is that the precise effect of the cloth in a finished state is accurately represented, the crisp transparent effect of a silk fabric being truly given, as well as the soft and more opaque effect of a woollen fabric.

This invention is new in principle, being a novel application of coloured glass to useful and essentially practical purposes.

PEARLASH, a commercial form of POTASH, which see.

PEARLS (*Perles* Fr.; *Perlen*, Germ.), are the productions of certain shell-fish. These molluscæ are subject to a kind of disease caused by the introduction of foreign bodies within their shells. In this case, their pearly secretion, instead of being spread in layers upon the inside of their habitation, is accumulated round these particles in concentric layers. Pearl consists of carbonate of lime, interstratified with animal membrane.

The oysters whose shells are richest in mother of pearl, are most productive of these highly prized spherical concretions. The most valuable pearl fisheries are on the coast of Ceylon, and at Olmutz in the Persian Gulf, and their finest specimens are more highly prized in the East than diamonds, but in Europe they are liable to be rated very differently, according to the caprice of fashion. When the pearls are large, truly spherical, reflecting and decomposing the light with much vivacity, they are much admired. But one of the causes which renders their value fluctuating, is the occasional loss of their peculiar lustre, without our being able to assign a satisfactory reason for it. Besides, they can be now so well imitated, that the artificial pearls have nearly as rich an appearance as the real.

PEARLS, ARTIFICIAL. These are small globules or pear-shaped spheroids of thin glass, perforated with two opposite holes, through which they are strung, and mounted into necklaces, &c., like real pearl ornaments. They must not only be white and brilliant, but exhibit the iridescent reflections of mother of pearl. The liquor employed to imitate the pearly lustre, is called the *essence of the East* (*essence d'orient*), which is prepared by throwing into water of ammonia the brilliant scales, or rather the *lamellæ*, separated by washing and friction, of the scales of a small river fish, the blay, called in French *ablette*. These scales digested in ammonia, having acquired a degree of softness and flexibility which allow of their application to the inner surfaces of the glass globules, they are introduced by suction of the liquor containing them in suspension. The ammonia is volatilized in the act of drying the globules.

It is said that some manufacturers employ ammonia merely to prevent the alteration of the scales; that when they wish to make use of them, they suspend them in a well clarified solution of isinglass, then pour a drop of the mixture into each bead, and spread it round the inner surface. It is doubtful whether, by this method, the same lustre and play of colors can be obtained as by the former. It seems moreover to be of importance for the success of the imitation, that the globules be formed of a bluish, opalescent, very thin glass, containing but little potash and oxide of lead. In every manufactory of artificial pearls, there must be some workmen possessed of great experience and dexterity. The French are supposed to excel in this ingenious branch of industry.

False pearls were invented in the time of Catherine de Medicis, by a person of the name of Jaquin. They are made of small globules of glass, blown by the ordinary lamp. The pearly lustre is communicated by introducing by means of a blow-pipe a small quantity of nacreous substances obtained from the surface of the scale of a small fish very common in the Seine and the Rhine, and also in the Thames. This substance preserved with sal ammoniac in a liquid state is commonly sold under the name of "Oriental essence;" after having covered the inside of the pearl with this liquid, a coating of wax is added, which is coloured to the required shade. The manufacture of pearls is principally carried on in the department of the Seine in France. There are also manufactories in Germany and Italy, but to a small extent. In Germany, or rather Saxony, a cheap but inferior quality is manufactured. The globe of glass forming the pearl in inferior ones being very thin, and coated with wax, they break on the slightest pressure. They are known by the name of German fish pearls; Italy also manufactures pearls by a method borrowed from the Chinese; they are known under the name of Roman pearls, and a very good imitation of natural ones; they have on their outside a coating of the nacreous liquid. The Chinese pearls are made of a kind of gum, and are covered likewise with the same liquid. In the year 1834 a French artisan dis-

covered an opaline glass of a nacreous or pearly colour, very heavy and fusible, which gave to the beads the different weights and varied forms found amongst real pearls: gum instead of wax is now used to fill them, by which they attain a high degree of transparency, and the glassy appearance has been lately obviated by the use of the vapour of hydro-fluoric acid. This acts in such a manner as to deaden the surface, and remove its otherwise glaring look.

PEARLS, ARTIFICIAL, and BEADS. The material out of which these are formed are small glass tubes like those with which thermometers are made. The tubes for the bright red pearls consist of two layers of glass, a white opaque one internally, and a red one externally; drawn from a ball of white enamel, coated in the Bohemian method with ruby-colored glass, either by dipping the white ball into a pot of red glass, and thus coating it, or by introducing the ball of the former into a cylinder of the latter glass, and then cementing them so soundly together as to prevent their separation in the subsequent pearl processes. These tubes are drawn in a gallery of the glasshouse to 100 paces in length, and cut into pieces about a foot long. These are afterward subdivided into cylindric portions of equal length and diameter, preparatory to giving them the spheroidal form. From 60 to 80 together are laid horizontally in a row upon a sharp edge, and then cut quickly and dexterously at once by drawing a knife over them. The broken fragments are separated from the regular pieces by a sieve. These cylinder portions are rounded into the pearl shape by softening them by a suitable heat, and stirring them all the time. To prevent them from sticking together, a mixture of gypsum and plumbago, or of ground clay and charcoal, is thrown in among them.

*Figs. 1049, 1050 represent a new apparatus for rounding the beads; fig. 1049 is a front view of the whole; fig. 1050 is a section through the middle of the former figure, in the course of its operation. The brick furnace, strengthened with iron bands, 2, 3, 5, 7, 8, has in its interior (see *fig. 1050*.) a nearly egg-shaped space *n*, provided with the following openings: beneath is the fire-hearth, *c*, with a round mouth, and opposite are the smoke flue and chimney, *p*; in the slanting front of the furnace is a large opening, *e*, *fig. 1049*. Beneath are two smaller oblong rectangular orifices, *r*, *g*, which extend somewhat obliquely into the laboratory, *v*. *n* serves for introducing the wood into the fireplace. All these four openings are, as shown in *fig. 1049*, secured from injury by iron mouth-pieces. The wood is burned upon an iron or clay bottom piece, *r*. A semi-circular cover, *n*, closes during the operation the large opening, *e*, which at other times remains open. By means of a hook, *m*, and a chain, which rests upon a hollow arch, *h*, the cover, *n*, is connected with the front end of the long iron lever, *n*, *n'*. A prop supports at once the turning axis of this lever and the catch, *b*, *c*; the weight, *q*, draws the arm *n* down, and thereby holds up *n*; *e* therefore remains open. By*

rods on the back wall, τ , τ , the hook i , in which κ' rests, proceeds from f . When κ' is raised κ sinks. The catch c b , enters with its front tooth into a slanting notch upon the upper edge of κ , spontaneously by the action of the spring e ; whereby the opening, κ , is shut. The small door κ , rises again with the front arm of the lever by the operation of the weight q of itself, as soon as the catch is released by pressure upon c .

The most important part of the whole apparatus is the drum, κ , for the reception and rounding of the bits of glass. It may be made of strong copper, or of hammered

or cast iron quite open above, and pierced at the bottom with a square hole, into which the lower end of the long rod, t , is exactly fitted, and secured in its place by a screwed collector nut. The blunt point, z , (*fig.* 1049.) rests during the working in a conical iron step of the laboratory, *fig.* 1050. On the mouth of the drum κ , a strong iron ring is fixed, having a bar across its diameter, with a square hole in its middle point, fitted and secured by a pin to the rod t , and turned by its rotation. The vessel κ , and its axle t , are laid in a slanting direction; the axle rests in the upper ring, z , at the lower end of the rod, l , of which the other end is hung to the hook, n , upon the mantel beam, κ . On the upper end of t , the handle, s , is fixed for turning round continuously the vessel, κ , while the fire is burning in the furnace, the fuel being put not only in its bottom chamber, but also into the holes, r , g (*fig.* 1049). The fire-wood is made very dry before being used, by piling it in logs upon

the iron bars, 2, 10, 11, under the mantelpiece, as shown in *figs.* 1049, 1050.

After the operation is finished, and the cover, n , is removed, the drum is emptied of its contents, as follows. Upon the axle, t , there is toward κ a projection at u . Alongside the furnace (*fig.* 1049) there is a crane, m , that turns upon the step s , s , on the ground. The upper pivot turns in a hole of the mantel-beam, κ . Upon the perpendicular arm, w , of the crane there is a hook, y , and a ring, q , in which the iron rod, p , is moveable in all directions. When the drum is to be removed from the furnace, the crane, with its arm, w , must be turned inward, the under hook of the rod, p , is to be hung in the projecting piece, u , and the rod, l , is lifted entirely out. After this, by means of the crane, the drum can be drawn with its rod, t , out of the furnace; and through the mobility of the crane, and its parts, p , q , any desired position can be given to the drum. *Fig.* 1049 shows how the workman can with his hand applied to s' depress the axle, t , and thereby raise the drum, κ , so high that it will empty itself into the pot, L , placed beneath. When left to itself, the drum on the contrary hangs nearly upright upon the crane by means of the rod, p , and may therefore be easily filled again in this position. The manner of bringing it into the proper position in the furnace by means of the crane and the rod, l , is obvious from *fig.* 1050.

The now well-rounded beads are separated from the pulverulent substance with which they were mixed, by careful agitation in sieves; and they are polished finally and cleaned by agitation in canvass-bags.

PEARL BUTTONS. Pearl-button making is thus practised; the blanks are cut out of the shell by means of a small revolving steel tube, the edge of which is toothed as a saw, after which they are flattened or reduced in thickness by splitting, which is aided by the laminar structure of the shell. At this stage being held in a spring chuck, they are finished on both sides by means of a small tool: the drilling is effected by the revolution of a sharp steel instrument, which acts with great rapidity. Ornamental cuttings are produced by means of small revolving cutters, and the final brilliant polish is given by the friction of rotten-stone and soft soap upon a revolving bench.

PEARL WHITE is a submuriate of bismuth, obtained by pouring a solution of the nitrate of that metal into a dilute solution of sea-salt, whereby a light and very white powder is obtained, which is to be well washed and dried. See **BISMUTH**.

PECTIC ACID (*Acide pectique*, Fr.; *Gallertsäure*, Germ.), so named on account of its jellying property, from *pectis*, *coagulum*, exists in a vast number of vegetables. The easiest way of preparing it, is to grate the roots of carrots into a pulp, to express their juice, to wash the *marc* with rain or distilled water, and to squeeze it well; 50 parts of the *marc* are next to be diffused through 300 of rain-water, adding by slow degrees a solution of one part of pure potash, or two of bicarbonate. This mixture is to be heated, so as to be made to boil for about a quarter of an hour, and is then to be thrown boiling-hot upon a filter cloth. It is known to have been well enough boiled, when a sample of the filtered liquor becomes gelatinous by neutralizing it with an acid. This liquor contains pectate of potassa, in addition to other matters extricated from the root. The pectate may be decomposed by a stronger acid, but it is better to decompose it by muriate of lime; whereby a pectate of lime, in a gelatinous form, quite insoluble in water, is obtained. This having been washed with cold water upon a cloth, is to be boiled in water containing as much muriatic acid as will saturate the lime. The pectic acid thus liberated, remains under the form of a colorless jelly, which reddens litmus paper, and tastes sour, even after it is entirely deprived of the muriatic acid. Cold water dissolves very little of it; it is more soluble in boiling water. The solution is colorless, does not coagulate on cooling, and hardly reddens litmus paper; but it gelatinizes when alcohol, acids, alkalis, or salts are added to it. Even sugar transforms it, after some time, into a gelatinous state, a circumstance which serves to explain the preparation of apple, cherry, raspberry, gooseberry, and other jellies.

PECTINE, or vegetable jelly, is obtained by mixing alcohol with the juice of ripe currants, or any similar fruit, till a gelatinous precipitate takes place; which is to be gently squeezed in a cloth, washed with a little weak alcohol, and dried. Thus prepared, pectine is insipid, without action upon litmus, in small pieces, semi-transparent, and of a membranous aspect, like isinglass. Its mucilaginous solution in cold water is not tinged blue with iodine. A very small addition of potash, or its carbonate, converts pectine into pectic acid; both of which substances are transformed into mucic and oxalic acids by the nitric.

PELTRY (*Pelleterie*, Fr.; *Pelzwerk*, Germ.), is nearly synonymous with fur, and comprehends the skins of different kinds of wild animals that are found in high northern latitudes, particularly in the American continent; such as the beaver, bear, moosedeer, marten, mink, sable, wolverine, wolf, &c. When these skins have received no preparation but from the hunters, they are most properly called peltry; but when they have had the inner side tawed or tanned (see **LEATHER**) by an aluminous process, they may then be denominated *furs*.

The scouring or cleaning of peltry is performed in a large cask, or truncated cone laid on its side, and traversed by a revolving shaft, which is furnished with a few rectangular rounded pegs. These are intended to stir round the skins, while they are dusted over with Paris plaster, whitening, or sometimes sand, made as hot as the hand can bear. The bottom of the cask should be grated, to allow the impurities to fall out. The *lustrage*, which the cleansed skins next undergo, is merely a species of dyeing, either topical, to modify certain disagreeable shades, or general, to impart a more beautiful color to the fur. Under the articles **DYEING**, and the several colors, as also **HAIR** and **MOROCCO**, sufficient instructions will be found for dyeing fur. The mordants should be applied pretty hot by a brush, on the hair of the skin, stretched upon a solid table; and after two or three applications, with drying between, the tinctorial infusions may be rubbed on in the same way. The hair must be freed beforehand from all greasiness, by lime water, or a weak solution of carbonate of soda; then well washed. Much nicety, and many successive applications of the dye-stuff, are sometimes requisite to bring out the desired shade.

Under **HAT MANUFACTURE**, I referred to this article for a description of the process of *secrelage*, whereby the hairs of rabbit and hare skins are rendered fit for felting. Dissolve 32 parts of quicksilver in 500 of common aquafortis; and dilute the solution with one half or two thirds of its bulk of water, according to the strength of the acid. The skin being laid upon a table with the hair side uppermost, a brush, made with the bristles of the wild boar, is to be slightly moistened with the mercurial solution, and passed over the smooth surface of the hairs with strong pressure. This application must be repeated several times in succession, till every part of the fur be equally touched, and till about two thirds of the length of the hairs be moistened, or a little more, should they be rigid. In order to complete this impregnation, the skins are laid together in pairs with the hairy sides in contact, put in this state into the stove-room, and exposed to a heat higher in proportion to the weakness of the mercurial solution. The drying should be rapidly effected, otherwise the concentration of the nitrate will not take due effect in causing the retraction and curling of the hairs.

No other acid, or metallic solution, but the above, has been found to answer the de

ured purpose of the hatmaker. After the hairs are properly *secreted*, they are plucked off by hand, or shorn off by a machine.

PENCIL MANUFACTURE. (*Crayons, fabrique de, Fr.; Bleistifte, verfertigung, Germ.*) The word pencil is used in two senses. It signifies either a small hair brush employed by painters in oil and water colors, or a slender cylinder, of black lead or plumbago, either naked or enclosed in a wooden case, for drawing black lines upon paper. The last sort, which is the one to be considered here, corresponds nearly to the French term *crayon*, though this includes also pencils made of differently colored earthy compositions. See *CRAYON*.

The best black-lead pencils of this country are formed of slender parallelipeds, cut out by a saw from sound pieces of plumbago, which have been previously calcined in close vessels at a bright red heat. These parallelipeds are generally enclosed in cases made of cedar wood, though of late years they are also used alone, in peculiar pencil-cases, under the name of ever-pointed pencils, provided with an iron wire and screw, to protrude a minute portion of the plumbago beyond the tubular metallic case, in proportion as it is wanted.

In the year 1795, M. Conté, a French gentleman, well acquainted with the mechanical arts, invented an ingenious process for making artificial black-lead pencils of superior quality, by which he and his successor and son-in-law, M. Humblot, have realized large fortunes.

Pure clay, or clay containing the smallest proportion of calcareous or silicious matter, is the substance which he employed to give aggregation and solidity, not only to plumbago dust, but to all sorts of colored powders. That earth has the property of diminishing in bulk, and increasing in hardness, in exact proportion to the degree of heat it is exposed to, and hence may be made to give every degree of solidity to crayons. The clay is prepared by diffusing it in large tubs through clear river water, and letting the thin mixture settle for two minutes. The supernatant milky liquor is drawn off by a syphon from near the surface, so that only the finest particles of clay are transferred into the second tub, upon a lower level. The sediment, which falls very slowly in this tub, is extremely soft and plastic. The clear water being run off, the deposit is placed upon a linen filter, and allowed to dry. It is now ready for use.

The plumbago must be reduced to a fine powder in an iron mortar, then put into a crucible, and calcined at a heat approaching to whiteness. The action of the fire gives it a brilliancy and softness which it would not otherwise possess, and prevents it from being affected by the clay, which it is apt to be in its natural state. The less clay is mixed with the plumbago, and the less the mixture is calcined, the softer are the pencils made of it; the more clay is used the harder are the pencils. Some of the best pencils made by M. Conté, were formed of two parts of plumbago and three parts of clay; others of equal parts. This composition admits of indefinite variations, both as to the shade and hardness; advantages not possessed by the native mineral. While the traces may be made as black as those of pure plumbago, they have not that glistening aspect which often impairs the beauty of black-lead drawings. The same lustre may, however, be obtained by increasing the proportion of powdered plumbago relatively to the clay.

The materials having been carefully sifted, a little of the clay is to be mixed with the plumbago, and the mixture is to be triturated with water into a perfectly uniform paste. A portion of this paste may be tested by calcination. If on cutting the indurated mass, particles of plumbago appear, the whole must be further levigated. The remainder of the clay is now to be introduced, and the paste is to be ground with a muller upon a porphyry slab, till it be quite homogeneous, and of the consistence of thin dough. It is now to be made into a ball, put upon a support, and placed under a bell glass inverted in a basin of water, so as to be exposed merely to the moist air.

Small grooves are to be made in a smooth board, similar to the pencil parallelipeds, but a little longer and wider, to allow for the contraction of volume. The wood must be boiled in grease, to prevent the paste from sticking to it. The above described paste being pressed with a spatula into these grooves, another board, also boiled in grease, is to be laid over them very closely, and secured by means of screw-clamps. As the atmospheric air can get access only to the ends of the grooves, the ends of the pencil-pieces become dry first, and by their contraction in volume get loose in the grooves, allowing the air to insinuate further, and to dry the remainder of the paste in succession. When the whole piece is dried, it becomes loose, and might be turned out of the grooves. But before this is done, the mould must be put into an oven moderately heated, in order to render the pencil pieces still drier. The mould should now be taken out, and emptied upon a table covered with cloth. The greater part of the pieces will be entire, and only a few will have been broken, if the above precautions have been duly observed. They are all, however, perfectly straight, which is a matter of the first importance.

In order to give solidity to these pencils, they must be set upright in a crucible till

it is filled with them, and then surrounded with charcoal powder, fine sand, or sifted wood ashes. The crucible, after having a luted cover applied, is to be put into a furnace, and exposed to a degree of heat regulated by the pyrometer of Wedgewood; which degree is proportional to the intended hardness of the pencils. When they have been thus baked, the crucible is to be removed from the fire, and allowed to cool with the pencils in it.

Should the pencils be intended for drawing architectural plans, or for very fine lines, they must be immersed in melted wax or suet nearly boiling hot, before they are put into the cedar cases. This immersion is best done by heating the pencils first upon a grid-iron, and then plunging them into the melted wax or tallow. They acquire by this means a certain degree of softness, are less apt to be abraded by use, and preserve their points much better.

When these pencils are intended to draw ornamental subjects with much shading, they should not be dipped as above.

Second process for making artificial pencils, somewhat different from the preceding.—All the operations are the same, except that some lamp-black is introduced along with the plumbago powder and the clay. In calcining these pencils in the crucible, the contact of air must be carefully excluded, to prevent the lamp-black from being burned away on the surface. An indefinite variety of pencils, of every possible black tint, may thus be produced, admirably adapted to draw from nature.

Another ingenious form of mould is the following:

Models of the pencil-pieces must be made in iron, and stuck upright upon an iron tray, having edges raised as high as the intended length of the pencils. A metallic alloy is made of tin, lead, bismuth, and antimony, which melts at a moderate heat. This is poured into the sheet-iron tray, and after it is cooled and concreted, it is inverted, and shaken off from the model bars, so as to form a mass of metal perforated throughout with tubular cavities, corresponding to the intended pencil-pieces. The paste is introduced by pressure into these cavities, and set aside to dry slowly. When nearly dry, the pieces get so much shrunk that they may be readily turned out of the moulds upon a cloth table. They are then to be completely desiccated in the shade, afterwards in a stove-room, next in the oven, and lastly ignited in the crucible, with the precautions above prescribed.

M. Conté recommends the hardest pencils of the architect to be made of lead melted with some antimony and a little quicksilver.

In their further researches upon this subject, M. Conté and M. Humblot found that the different degrees of hardness of crayons could not be obtained in a uniform manner by the mere mixture of plumbago and clay in determinate doses. But they discovered a remedy for this defect in the use of saline solutions, more or less concentrated, into which they plunged the pencils, in order to modify their hardness, and increase the uniformity of their texture. The non-deliquestent sulphates were preferred for this purpose; such as sulphate of soda, &c. Even sirup was found useful in this way.

Messrs. Stevens and Wylder's pencils, pens, and pen holders.—Messrs. Stevens & Wylder obtained a patent in June, 1850, for certain improvements, in which they claim,

1. (In respect of ever pointed pencils.) The employment of an internal helix in lieu of a propelling screw, by means of which a length of black lead, chalk, or other marking materials may be propelled nearly the whole length of the pencil.

2. (With reference to pens.) The application of gutta percha to metal pens, between the shoulder and the nib, the metal having been first reduced in thickness, either by grinding or otherwise, for the purpose of obtaining greater flexibility.

2ndly. The construction of barrel and other pens in metal, to be used with fountain pen holders, having the barrel placed the reverse way, or above instead of below the nib.

3. (With respect to penholders.) 1st. The use and application of glass to telescopic and other fountain holders, whereby the ink is kept from contact with metal until it reaches the pen. (Query, has not this been anticipated by Mr. Thomson's patent?) 2ndly. The adaptation of a band of flexible material to fountain holders, for the purpose of facilitating the flow of ink to the pen, such band being placed around a part of the tube, in which air holes or openings have been previously made.

PENS, STEEL. The best metal, made from Dannemora or hoop (L) iron, is selected and laminated into slips about 3 feet long, and 4 inches broad, of a thickness corresponding to the desired stiffness and flexibility of the pens. These slips are subjected to the action of a stamping-press, somewhat similar to that for making buttons. (See **BUTTON** and **PLATED WARE**.) The point destined for the nib is next introduced into an appropriate gauged hole of a little machine, and pressed into the semi-cylindrical shape; where it is also pierced with the middle slit, and the lateral ones, provided the pen is to be given. The pens are now cleaned, by being tossed about among each other in a tin cylinder, about 3 feet long, and 9 inches in diameter; which is suspended by two joints to two cranks, formed one on each of two shafts. The cylin-

der, by the rotation of a fly-wheel, acting upon the crank-shafts, is made to describe such revolutions as agitate the pens in all directions, and polish them by mutual attrition. In the course of 4 hours several thousand pens may be finished upon this machine.

When steel pens have been punched out of the softened sheet of steel by the appropriate tool, fashioned in the desired form, and hardened by ignition in an oven and sudden quenching in cold water, they are best tempered by being heated to the requisite spring elasticity in an oil bath. The heat of this bath is usually judged of by the appearance to the eye; but this point should be correctly determined by a thermometer, according to the scale (see STEEL); and then the pens would acquire a definite degree of flexibility or stiffness, adapted to the wants and wishes of the consumers. They are at present tempered too often at random.

Gillott, Joseph, Victoria Works, Birmingham, Inventor and Manufacturer. Specimens of metallic pens. Steel pen making may be briefly described as follows: The steel is procured at Sheffield; it is cut into strips, and the scales removed by immersion in pickle composed of dilute sulphuric acid. It is passed through rollers, by which it is reduced to the necessary thickness; it is then in a condition to be made into pens, and is for this purpose passed into the hands of a girl, who is seated at a press, and who by means of a bed and a punch corresponding speedily cuts out the blank. The next stage is piercing the hole which terminates the slit and removing any superfluous steel likely to interfere with the elasticity of the pen; at this stage they are annealed in quantities in a muffle, after which by means of a small stamp the maker's name is impressed upon them. Up to this stage the future pen is a flat piece of steel: it is then transferred to another class of workers, who by means of the press make it concave, if a nib, and form the barrel, if a barrel pen. Hardening is the next process: to effect this a number of pens are placed in a small iron box and introduced into a muffle; after they become of a uniform deep red, they are plunged into oil; the oil adhering is removed by agitation in circular tin barrels. The process of tempering succeeds; and finally the whole are placed in a revolving cylinder with sand, pounded crucible, or other cutting substances, which finally brightens them to the natural colour of the material. The nib is ground with great rapidity by a girl who picks it up, places it in a pair of suitable plyers, and finishes it with a single touch on a small emery wheel. The pen is now in a condition to receive the slit, and this is also done by means of a press; a chisel or wedge with a flat side is fixed to the bed of the press; the descending screw has a corresponding chisel cutter, which passes down with the minutest accuracy; the slit is made; and the pen is completed. The last stage is colouring brown or blue; this is done by introducing the new pens into a revolving metal cylinder, under which is a charcoal stove, and watching narrowly when the desired tint is arrived at. The brilliancy is imparted by means of lac dissolved in naphtha; the pens are immersed in this, and dried by heat. Then follow the counting and selecting. Women are mostly employed in the manufacture, with skilled workmen to repair and set the tools. This exhibitor employs upwards of five hundred hands, of which four-fifths are women. The manufactory has been established upwards of thirty years, and has been the means of introducing many improvements in the manufacture.

Wiley, W. E. & Co., 34 Great Hampton Street, Birmingham—Manufacturer. Specimens of gold, palladium, gold and silver, and silver pens, pointed with the native alloys of iridium and osmium, the hardest of metals.

These pens, being formed of metals not acted on by the ink, appear almost indestructible; their permanence in use is further maintained by the attachment to the point, by soldering, of a minute portion of the metals named, which are extremely hard and durable.

Hincks, Wells, & Co., Buckingham street, Birmingham—Manufacturers. Patent self-acting cutting, piercing, and raising pen machine. The ordinary presses are worked by hand. The self-acting machines are driven by steam; they cut, pierce, and slide slit two pens at one stroke, performing six processes at once.

Specimens of liliputian pens complete, intended to show the skill of the tool cutter and the perfection of the machinery employed. A gross of the smallest weighs less than 34 grains, and can be contained in a barcelona nutshell.

Specimens of finished pens. Steel in its rough state, and after it has passed through the rolling-mill; scrap steel from which the pens are cut; pens cut and pierced. The other processes exhibited in the finished pen.

Specimens of pierced pens, to show the modern improvements in the art of tool-cutting.

PEPPER. (*Poirre*, Fr.; *Pfeffer*, Germ.). Black pepper is composed, according to M. Pelletier, of the vegetable principle, *piperine*, of a very acrid concrete oil, a volatile balsamic oil, a coloured gummy matter, an extractive principle analogous to legumine, malic and tartaric acids, starch, bassorine, ligneous matter, with earthy and alkaline salts in small quantity. Cubebs pepper has nearly the same composition.

PEPPER. The unripe grains or corns are known under the name of black pepper; the ripe ones, deprived of their epidermis, constitute white pepper. The latter are very generally bleached by steeping for a little while in a solution of chloride of lime, subsequent washing and drying; a process which improves their aspect, but not their flavor. I was recently led to examine the nature of this substance somewhat minutely, from being called professionally to investigate a sample of ground white pepper belonging to an eminent spice-house in the city of London, which pepper had been seized by the Excise on the charge of its being adulterated, or mixed with some foreign matter, contrary to law. I made a comparative analysis of that pepper and of genuine white pepper-corns, and found both to afford like results: viz. in 100 grains, a trace of volatile oil, in which the aroma chiefly resides; about $8\frac{1}{2}$ grains of a pungent resin, containing a small fraction of a grain of piperine; about 60 grains of starch, with a little gum, and nearly 30 grains of matter insoluble in hot and cold water, which may be reckoned lignine. The two chemists in the service of the Excise made oath before the court of judicature, that the said pepper contained a notable proportion of sago, even to the amount of fully 10 per cent.; grounding their judgment upon the appearance of certain rounded particles in the pepper, and of the deep blue color which these assumed when moistened with iodine water. No allegation could be more frivolous. Bruised corns of genuine white pepper certainly acquire as deep a tint with iodine as any species of starch whatever. But the characters of sago, optical and chemical, are so peculiar, as to render the above surmise no less preposterous, than the prosecution of respectable merchants, for such a cause, was unjustifiable. A particle of sago appears in the microscope, by reflected light, to be a spherule of snow, studded round with brilliants; whereas the rounded particles of the seized pepper seem to be amorphous bits of gray clay. Had the pepper been adulterated with such a quantity of sago, or anything else, as was alleged, it could not have afforded me, by digestion in alcohol, as much of the spicy essence as the bruised genuine pepper-corns did.

Moreover, sago, steeped for a short time in cold water, swells and softens into a pulpy consistence, whereas the particles of the seized pepper, rounded by attrition in the mill, retain, in like circumstances, their hardness and dimensions. Sago, being pearly by heating and stirring the fine starch of the sago palm in a damp state, upon iron or other plates, acquires its peculiar somewhat loose aggregation and brilliant surface; while, in pepper, the starchy constituent is compactly condensed, and bound up with its ligneous matter.

The Excise laws are sufficiently odious and oppressive in themselves without being aggravated by the servile sophistry of pseudo-science.

Four pounds of black pepper yield only about one ounce of piperine, or one 636th part. It is an insipid crystalline substance, insoluble in water, but very soluble in boiling alcohol, and is extracted at first along with the resin, which may be separated from it afterward, by potash.

PERCUSSION CAPS, Patent. The total manufacture of percussion caps for sporting guns in Europe may be estimated at 1,300,000,000 yearly. Some idea of the importance of this article may be formed from the quantity of copper requisite for its production, viz 396,000 lbs. weight. The great advantages of the percussion principle have been so generally acknowledged, that within the short space of 20 years all kinds of guns with flint-locks have been abandoned, and the percussion system has likewise been extended to muskets for the army. The percussion caps exhibited are stated to be remarkable for accuracy and equality of bore, for the malleability of the copper, and superior quality of the powder. The percussion caps coated with varnish exhibited may remain in water for 72 hours and more without losing their power of immediately igniting the powder.

Nipples (*pistons*) hermetically closed, a new invention which prevents any moisture from penetrating between the percussion caps and the nipple, and thus preserves the powder perfectly dry.

PERFUMERY, ART OF (*Parfumerie*, Fr.; *Wohlrichende-kunst*, Germ.); consists in the preparation of different products, such as fats or pommandes, essential oils, distillates, pastes, pastilles and essences.

Fats ought to be pounded in a marble mortar, without addition of water, till all the membranes be completely torn; then subjected to the heat of a water-bath in a proper vessel. The fat soon melts, and the albumen of the blood coagulating, carries with it all the foreign substances; the liquid matter should be skimmed, and passed through a canvass filter.

Of pommades by infusion.—Rose, orange-flower, and cassia. Take 334 pounds of hog's lard, and 166 of beef suet. These 500 pounds are put into a pan called *bugadier*; and when melted, 150 pounds of rose-leaves nicely plucked are added, taking care to stir the mixture every hour. The infusion thus prepared is to remain at rest for 24 hours; at the end of this time, the pommade is again melted, and well stirred to prevent its adherence to the bottom of the melting-pan. The mass is now to be poured out into canvass, and made into rectangular bricks or loaves, which are subjected to a press, in order to separate the solid matter from the soft pommade. These brick-shaped pieces being put into an iron-bound barrel perforated all over its staves, the pommade is to be allowed to exude on all sides, and flow down into a copper vessel placed under the trough of the press. This manipulation should be repeated with the same fat ten or twelve times; or in other words, 3000 pounds of fresh rose-leaves should be employed to make a good pommade.

The pommade of orange-flowers is made in the same manner, as also the pommade of cassia.

Of pommades without infusion.—Jasmine, tuberose, jonquil, narcissus, and violet.

A square frame, called *fiame*, is made of four pieces of wood, well joined together, 2 or 3 inches deep, into which a pane of glass is laid, resting upon inside ledges near the bottom. Upon the surface of the pane the simple pommade of hog's lard and suet is spread with a pallet knife; and into this pommade the sweet-scented flowers are stuck fresh in different points each successive day, during two or three months, till the pommade has acquired the desired richness of perfume. The above-described frames are piled closely over each other. Some establishments at *Grasse* possess from 3000 to 4000 of

Of oils.—Rose, orange-flower, and cassia oils, are made by infusion, like the pommades of the same perfumes; taking care to select oils perfectly fresh. As to those of jasmine, tuberose, jonquil, violet, and generally all delicate flowers, they are made in the following manner. Upon an iron frame, a piece of cotton cloth is stretched, imbued with olive oil of the first quality, and covered completely with a thin bed of flowers. Another frame is similarly treated, and in this way a pile is made. The flowers must be renewed till the oil is saturated with their odor. The pieces of cotton cloth are then carefully pressed to extrude the oil. This last operation requires commonly 7 or 8 days.

Of distillation.—The essential oils or essences, of which the great manufacture is in the south of France, are of rose, neroli, lavender, lemon thyme, common thyme, and rosemary. For the mode of distilling the essential oils, see OILS, ESSENTIAL.

The essence of roses being obtained in a peculiar manner, I shall describe it here. Put into the body of a still 40 pounds of roses, and 60 quarts of water; distil off one half of the water. When a considerable quantity of such water of the first distillation is obtained, it must be used as water upon fresh rose-leaves; a process of repetition to be carried to the fifth time. In the distillation of orange-flower, to obtain the essence of neroli, the same process is to be followed; but if orange-flower water merely be wanted, then it is obtained at one distillation, by reserving the first fifth part of water that comes over. What is called the essence of *petit-grain*, is obtained by distilling the leaves of the orange shrub. The essences of lavender, thyme, &c., present nothing peculiar in their mode of extraction.

OF SCENTED SPIRITS,

From oil of rose, orange, jasmine, tuberose, cassia, violet, and other flowers.

Into each of three digesters, immersed in water-baths, put 25 lbs. of any one of these oils, and pour into the first digester 25 quarts of spirit of wine; agitate every quarter of an hour during three days and at the end of this period, draw off the perfumed spirit, and

Esprit de Suave.

7 Eng. qrts. of spirit of jasmine, 3d operation.

7 — cassia, —

3 — wine, —

2 — tuberose, —

1½ ounce essence of cloves.

½ ounce fine neroli.

1½ ounce essence of bergamot.

8 ounces essence of musk, 2d infusion.

3 quarts rose water.

Spirit of Cytherea

1 quart spirit of violets.

1 — jasmine, 2d operation

1 — tuberose,

1 — clove gillyflower.

1 — roses, 2d operation.

1 — Portugal.

2 — orange-flower water

pour it into the second digester; then transfer it after 3 days into the third digester treating the mixture in the same way; and the spirit thus obtained will be perfect. The digesters must be carefully covered during the progress of these operations. On pursuing the same process with the same oil and fresh alcohol, essences of inferior qualities may be obtained, called Nos. 2, 3, and 4.

Some perfumers state that it is better to use highly scented pommades than oils; but there is probably little difference in this respect.

Spirit of flowers of Italy.

2 quarts spirit of jasmine, 2d operation.	2 quarts spirit of cassia, 2d operation.
2 — — roses, —	1½ — — orange flower water.
2 — — oranges, 3d —	

The above spirits mark usually 28 alcometric degrees of Gay Lussac. See ALCOHOL.

POMMADES.

No less than 20 scented pommades are distinguished by the perfumers of Paris. The essences commonly employed in the manufacture of pommades, are those of bergamot lemons, *cidrat*, *limette* (sweet lemon), Portugal, rosemary, thyme, lemon thyme, lavender, marjoram, and cinnamon.

The following may serve as an example:—

Pommade à la vanille, commonly called Roman.

12 pounds of pommade à la rose.

3 — — oil à la rose.

1 — — vanilla, first quality, pulverized.

6 ounces bergamot.

The pommade being melted at the heat of a water-bath, the vanilla is to be introduced with continual stirring for an hour. The mixture is left to settle during two hours. The pommade is then to be drawn off, and will be found to have a fine yellow color, instead of the brown shade which it commonly has.

In making odoriferous extracts and waters, the spirits of the flowers prepared by macerating the flowers in alcohol should be preferred to their distillation, as forming the foundation of good perfumery. The specific gravity of these spirits should be always under 0.88.

Extract of Nosegay (bouquet).

2 quarts spirit of jasmine, 1st operation.	
2 — — extract of violets.	
1 — — spirit of cassia, 1st —	
1 — — roses, — 1st —	
1 — — orange, — 1st —	
1 — — Extract of clove gillyflower.	
4 drms. of flowers of benzoin (benzoic acid).	
8 ounces of essence of amber, 1st infusion.	

Extract of peach blossoms.

6 quarts of spirits of wine.
6 pounds of bitter almonds.
2 quarts of spirits of orange flower, 2d operation.
4 drachms of essence of bitter almonds.
4 drachms of balsam of Peru.
4 ounces of essence of lemons.

Eau de Cologne.

Two processes have been adopted for the preparation of this perfume, distillation at infusion; the first of which, though generally abandoned, is, however, the preferable one. The only essences which should be employed, and which have given such celebrity to this water, are the following; bergamot, lemon, rosemary, Portugal, neroli. The whole of them ought to be of the best quality, but their proportions may be varied according to the taste of the consumers.

Thirty different odors are enumerated by perfumers; the three following recipes will form a sufficient specimen of their combinations.

Honey-water.

6 quarts of spirit of roses, 3d operation.
3 do — — jasmine.
3 do. — — spirits of wine.
3 ounces essence of Portugal.
4 drachms flowers of benzoin.
12 ounces of essence of vanilla, 3d infusion.
12 do. — — musk, do.
3 quarts good orange-flower water.

Eau de mille fleurs.

18 quarts of spirits of wine.
4 ounces balsam of Peru.
8 do. — — essence of bergamot.
4 do. — — cloves.
1 do. — — ordinary neroli.
1 do. — — thyme.
8 do. — — musk, 3d infusion.
4 quarts orange flower water.

Eau de mousseline.

2 quarts spirit of roses, 3d infusion.	2 ounces essence of vanilla, 3d infusion.
2 do. jasmine, 4th do.	2 do. musk, do.
1 do. clove gillyflower.	4 drachms of sanders wood.
2 do. orange flower, 4th do	1 quart of orange-flower water.

Almond pastes.

These are, gray, sweet white, and bitter white.

The first is made either with the kernels of apricots, or with bitter almonds. They are winnowed, ground, and formed into loaves of 5 or 6 pounds weight, which are put into the press in order to extract their oil; 300 pounds of almonds affording about 130 of oil. The pressure is increased upon them every two hours during three days; at the end of which time the loaves or cakes are taken out of the press to be dried, ground, and sifted.

The second paste is obtained by boiling the almonds in water till their skins are completely loosened; they are next put into a basket, washed and blanched; then dried, and pressed as above.

The third paste is prepared like the second, only using bitter almonds.

Liquid almond pastes, such as those of the rose, orange, vanilla, and nosegay. The honey paste is most admired. It is prepared as follows;—

6 pounds of honey.	12 pounds oil of bitter almonds.
6 do. white bitter paste.	26 yolks of eggs.

The honey should be heated apart and strained; 6 pounds of almond paste must then be kneaded with it, adding towards the conclusion, alternately, the quantity of yolks of eggs and almond oil indicated.

Pastilles à la rose, orange flower, and vanilla.

<i>Pastilles à la rose.</i>		<i>Pastilles of orange flower.</i>	
12 ounces of gum.		12 ounces of gum galbanum.	
12 do. olibanum, in tears.		12 do. olibanum, in tears.	
12 do. storax, do.		12 do. storax, do.	
8 do. nitre.		8 do. nitre.	
16 do. powder of pale roses.		1 pound of pure orange powder.	
3 pounds 14 do. charcoal powder.		3 do. 14 ounces charcoal powder.	
1 do. essence of roses.		1 ounce superfine neroli.	

Pastilles à la vanille.

12 ounces of gum galbanum.	16 ounces powder of vanilla.
12 do. olibanum, in tears.	3 pounds 14 ounces charcoal powder.
12 do. storax do.	4 drms. essence of cloves.
8 do. nitre.	8 ounces do. vanilla, 1st infusion.
8 do. cloves.	

The above mixture in each case is to be thickened with 2 ounces of gum tragacanth dissolved in 2 pints of rose water. It is needless to say that the ingredients of the mixture should be impalpable powders.

Scented cassolettes.

8 pounds of black amber (ambergris).	1 ounce essence of roses.
4 do. rose powder.	1 do. gum tragacanth.
2 ounces of benzoin.	A few drops of the oil of sanders wood.

These ingredients are pulverized, and made into a cohesive paste with the gum.

ESSENCES BY INFUSION.

Essence of musk.

5 ounces of musk from the bladder, cut small.
1 do. civet.
4 quarts of spirit of ambrette (purple sweet sultan).

The whole are put into a matrass, and exposed to the sun for two months during the hottest season of the year. In winter, the heat of a water bath must be resorted to.

Essence of vanilla.

3 pounds of vanilla in branches, 1st quality, cut small.
 4 quarts spirit of ambrette.
 2 drachms of cloves.
 $\frac{1}{4}$ do musk from the bladder.

The same process must be followed as for the essence of musk.

Essence of ambergris.

4 ounces of ambergris,	8 quarts of spirit of ambrette.
2 ounces of bladder musk.	Treat as above.

Spirit of ambrette (purple sweet sultan).

25 pounds of ambrette are to be distilled with 25 quarts of spirits of wine, adding 12 quarts of water, so as to be able to draw off the 25 quarts.

Artificial Essences of Fruits in the Exhibition. The artificial production of aromatic oils, for industrial objects, can only be traced back a few years. Young, however, as this manufacture is, it appears, nevertheless, to have been in the hands of several distillers, by whom a very considerable amount has been produced. Upon this point the jury became fully convinced by their investigations in this department; both in the English and in the French divisions of the Exhibition a large selection of these chemical perfumeries were to be found, the comparison of which at the same time with other aromatic preparations was satisfactorily illustrated. Most of these oils are poisonous in small quantities, so that in very few instances can their action be asserted without fresh investigations.

The commonest of these preparations was the pear-oil (Birñöl), a favourite fluid, which, by examination, is proved to be an alcoholic solution of acetate of the oxide of amyle. As the author had not sufficient of this satisfactorily to determine its composition by its combustion, he mixed it with potash, by which means fusel oil was immediately liberated, and the acetic acid was separated in the form of salt of silver, of which 0.3089 grammes gave 0.1994 grammes silver; the percentage of silver in the acetate being theoretically 64.68, by experiment 64.55. The acetate of oxide of amyle made according to the usual process (1 part sulphuric acid, 1 part fusel oil, and 2 parts of acetate of potash), presents a strong fruity odour, and by the addition of about 6 parts of alcohol, yields the flavour of jargonelle pear. Upon closer inquiry of the manufacturers of this substance the author found that it was produced in very considerable quantities (by some between 15 and 20 lbs. weekly). In England it is extensively employed in flavouring 'pear-drops,' which have almost superseded the common 'barley-sugar drops.'

Next to the "pear" oil, figures *Apple oil*, which experiment has shown to be nothing more than a valerianate of oxide of amyle, which yields an insupportable odour of rotten apples, pervading the laboratory where valerianic acid is produced. If the crude product of distillation be treated with a solution of potash, the valerianic acid is removed and the ether is retained; the addition to this of 5 or 6 times its volume of alcohol gives off an agreeable odour of apples.

The essence, however, which was observed to be in the greatest abundance was the "*Pine Apple oil*," which is simply a butyrate of oxide of ethyle. This composition, like the two preceding, yields its flavour on the addition of alcohol. The butyric ether, which in Germany is added to inferior sorts of rum, for the purpose of imparting a flavour to a peculiar kind of drink (pine apple ale), is seldom prepared for this purpose from pure butyric acid, but from the saponified acid, and the distillation of the soap with concentrated sulphuric acid and alcohol (vide *Annalen der Chemie und Pharmacie*, xlix. 359.) The fluid thus obtained contains other kinds of ether besides butyric ether, but may, without these, be employed for flavouring. The analysis of this ether by means of potash and a salt of silver, gave 0.4404 gr. of salt of silver; 0.2437 silver; the percentage of silver in its butyrate being, theoretically, 55.38, experimentally, 55.33.

The so-called *Cognac oil* and *Grape oil* were contributed to both the English and French departments. They are most frequently employed for giving the cognac flavour to brandies. The grape oil consists of a compound of amyle dissolved in alcohol, then set free by the addition of concentrated sulphuric acid; the oil of sulphate of amyle is then freed from alcohol by washing with water. Analysed by means of a salt of barium 1.2690 gr. amyl-sulphate of baryta gave 0.5815 gr. of sulphate of baryta, equal to 45.82 per cent. of sulphate of baryta. According to Cahours, and again more lately, according to Kekule, the analysis of amyl-sulphate of baryta with 2 eq. of water, contains 49.95 per cent. of sulphate of baryta. It is certainly remarkable, as has been observed, that we have here a body, which is most carefully excluded from brandy

on account of its intolerable odour, employed again under another form to give it flavour.

The next object of attention is the *artificial oil of bitter almonds*. When Mitscherlich, in 1834, discovered nitro-benzule, he did not foresee the great amount in which this body would be found in an Industrial Exhibition. It is true he had observed the remarkable similarity of its odour to that of oil of bitter almonds, but then the only source whence the nitro-benzule could be obtained, viz., from the oil of compressed gases, and the distillation of benzoic acid, were too costly to admit of the idea of its employment as a substitute for oil of bitter almonds. It remained for the author, in 1845, to detect the presence of benzule in the transformation of coal tar; and in 1849, Mansfield (*Chemical Society's Quarterly Journal*, i., 244.; *Annalen*, lxi. 162.) showed that it could be obtained with facility in considerable quantities from coal tar. The Great Exhibition has shown that this statement has not been lost sight of. In the French department of perfumery, it was met with under the designation of artificial oil of bitter almonds, and under the fantastic name of essence of mirbane, varieties of the oil which, on examination, were found to be more or less pure nitro-benzule. In London it is used in large quantities. Messrs. Mansfield's simple apparatus for its preparation is thus described:—A large glass worm is used, the upper end of which is bifurcated, and forms two tubes of a funnel shape; into one of these funnels concentrated nitric acid is poured, in the other the benzule is placed (and for this purpose it is not required to be absolutely pure). The two bodies, therefore, meet at the point of junction of these two tubes, the compound is cooled by its course through the windings of the worm, and requires only to be washed with water or diluted solution of carbonate of soda, and it is then fit for use. Although nitro-benzule has an odour so closely resembling oil of bitter almonds, a difference may be detected by an experienced nose. It is, however, very generally employed in scenting soaps, in confectionery, and for culinary purposes. For the last named purpose it has the advantage of not containing hydrocyanic acid.

Besides the preceding, many other substances of analogous nature were exhibited, but they were of too complicated characters to be satisfactorily examined in the small quantities to be met with. In many of these essences there was, however, a great similarity of aroma.

PERFUMERY, INDIAN. The natives place on the ground a layer of the scented flowers, about 4 inches thick and 2 feet square; cover them over with a layer 2 inches thick of *Tel* or Sesamum seed wetted; then lay on another 4 inch bed of flowers, and cover this pile with a sheet, which is pressed down by weights round the edges. After remaining in this state for 18 hours, the flowers are removed and replaced by a similar fresh layer, and treated as before; a process which is repeated a third time if a very rich perfumed oil be required. The sesamum seeds thus imbued with the essential oil of the plant, whether jasmine, Bela, or Chumbul, are placed in their swollen state in a mill, and subjected to strong pressure, whereby they give out their bland oil strongly impregnated with the aroma of the particular flower employed. The oil is kept in prepared skins called *dubbers*, and is largely used by the Indian women. The attar of roses is obtained by distillation at a colder period of the year.

PERRY, is the fermented juice of pears, prepared in exactly the same way as CYDER.

PERSIAN BERRIES. See BERRIES, PERSIAN.

PERSONAL CLOTHING. The title of the class will suggest the multifarious objects which fall naturally within its comprehensive limits. The sub-classes are as follows:—A. hats, caps, and bonnets of various materials; B. hosiery, of cotton, woollen, and silk; C. gloves of leather and other materials; D. boots, shoes, and lasts; E. under-clothing; F. upper-clothing.

The manufactories of hosiery, straw plait, and boots and shoes, have a local establishment in this country, which is deserving of attention; that of hosiery is principally confined to Derby, Nottingham, and Leicester. Cotton hosiery is chiefly made in Nottingham, as also is the silk hosiery; the latter being likewise largely conducted in Derby. Woollen hosiery is most extensively produced in Leicestershire. The statistics of these trades have been carefully prepared and are very interesting. The annual value of cotton hosiery is taken at 880,000*l.*, that of worsted, &c., is 870,000*l.*, and of silk, 241,000*l.* In the manufacture of these goods it is estimated that 4,584,000 lbs. of raw cotton wool are used,—6,318,000 lbs. of English wool, and 140,000 lbs. of silk. The total number of persons deriving support from the manufacture is about 73,000, and about 1,050,000*l.* of floating capital is considered to be employed in the various branches of the trade.

The manufacture of straw plait is carried on chiefly at St. Alban's, Dunstable, Tring, and a few other places. That of boots and shoes is conducted on a very large scale at Northampton, from which place vast quantities of these articles are sent out ready for wear. Worcester, Dundee, and Woodstock are celebrated for their glove manufactories.

Gloves are of great antiquity in this island, as the word is evidently derived from the Anglo-Saxon "glof." They are not mentioned in Scripture, but were in use among the Romans in the time of Pliny the Younger. Xenophon states that their use among the Persians was considered a proof of their luxurious habits. Gloves have had many symbolical meanings. The gauntlet or glove thrown down was a mode of challenge, and still is practised as one of the forms of royal coronation. Queen Elizabeth, it is well known, was very fond of gloves, of which numerous presents were made to her. White gloves are also presented to the judges on occasion of a maiden assize, the exact significance or origin of which practice has never been satisfactorily explained. Leather gloves are now made at Worcester, Yeovil, Woodstock, and London, and were formerly made at Leominster and Ludlow, but the trade in the latter places is quite decayed.

Plait straw is the straw of the wheat plant, selected especially from crops grown on dry chalky lands, such as those about Dunstable. The middle part of the straw above the last joint is selected; it is cut into lengths of eight or ten inches, and these are then split. The Leghorn or Tuscan is the straw of a variety of bearded wheat, grown expressly on poor sandy soils, pulled when green, and then bleached. Other kinds of the grass tribe besides wheat furnish straws available for plait-work.

PETROLEUM. See NAPHTHA.

PE-TUNT-SE, is the Chinese name of the fusible earthy matter of their porcelain. It is analogous to our Cornish stone.

PEWTER, PEWTERER. (*Polier d'étain*, Fr.) Pewter is, generally speaking, an alloy of tin and lead, sometimes with a little antimony or copper, combined in several different proportions, according to the purposes which the metal is to serve. The English tradesmen distinguish three sorts, which they call plate, trifle, and ley pewter; the first and hardest being used for plates and dishes; the second for beer-pots; and the third for larger wine measures. The plate pewter has a bright silvery lustre when polished; the best is composed of 100 parts of tin, 8 parts of antimony, 2 parts of bismuth, and 2 of copper. The trifle is said by some to consist of 83 of tin, and 17 of antimony; but it generally contains a good deal of lead. The ley pewter is composed of 4 of tin, and 1 of lead. As the tendency of the covetous pewterer is always to put in as much of the cheap metal as is compatible with the appearance of his metal in the market, and as an excess of lead may cause it to act poisonously upon all vinegars and many wines, the French government long ago appointed Fourcroy, Vauquelin, and other chemists, to ascertain by experiment the proper proportions of a safe pewter alloy. These commissioners found that 18 parts of lead might, without danger of affecting wines, &c., be alloyed with 82 parts of tin; and the French government in consequence passed a law requiring pewterers to use $83\frac{1}{2}$ of tin in 100 parts, with a tolerance of error amounting to $1\frac{1}{2}$ per cent. This ordinance, allowing not more than 18 per cent. of lead at a maximum, has been extended to all vessels destined to contain alimentary substances. A table of specific gravities was also published, on purpose to test the quality of the alloy; the density of which, at the legal standard, is 7.764. Any excess of lead is immediately indicated by an increase in the specific gravity above that number.

The pewterer fashions almost all his articles by casting them in moulds of brass or bronze, which are made both inside and outside in various pieces, nicely fitted together, and locked in their positions by ears and catches or pins of various kinds. The moulds must be moderately heated before the pewter is poured into them, and their surfaces should be brushed evenly over with pounce powder (sandarach) beaten up with white of egg. Sometimes a film of oil is preferred. The pieces, after being cast, are turned and polished; and if any part needs soldering, it must be done with a fusible alloy of tin, bismuth, and lead.

Britannia metal, the kind of pewter of which English tea-pots are made, is said to be an alloy of equal parts of brass, tin, antimony, and bismuth; but the proportions differ in different workshops, and much more tin is commonly introduced. Queen's metal is said to consist of 9 parts of tin, 1 of antimony, 1 of bismuth, and 1 of lead; it serves also for teapots and other domestic utensils.

A much safer and better alloy for these purposes may be compounded by adding to 100 parts of the French pewter, 5 parts of antimony, and 5 of brass to harden it. The English ley pewter contains often much more than 20 per cent. of lead. Under TIN, will be found the description of an easy method of analyzing its lead alloys.

PHANTASMAGORIA. The phantasmagoria lanterns are a scientific form of magic lantern, differing from it in no essential principle. The images they produce are variously exhibited, either on opaque or transparent screens. The light is an improved kind of solar lamp. The manner in which the beautiful melting pictures called dissolving views are produced, as respects the mechanism employed deserves to be explained. The

arrangement adopted in the instrument is the following:—Two lanterns of the same size and power, and in all respects exactly agreeing, are arranged together upon a little tray or platform. They are held fast to this stand by screws, which admit of a certain degree of half-revolving motion from side to side, in order to adjust the foci. This being done in such a manner that the circle of light of each lantern falls precisely upon the same spot upon the screen, the screws are tightened to the utmost extent so as to remove all possibility of further movement. The dissolving apparatus consists of a circular tin plate japanned in black, along three parts of the circumference of which a crescented aperture runs, the interval between the horns of the crescent being occupied by a circular opening, covered by a screwed plate, removable at pleasure. This plate is fixed to a horizontal wooden axis, at the other end of which is a handle, by which the plate can be caused to rotate. The axis of wood is supported by two pillars connected with a flat piece which is secured to the tray. This apparatus is placed between the lanterns in such a manner that the circular plate is in front of the tubes of both, while the handle projects behind the lanterns at the back. The plate can, therefore, be turned round by means of the handle without difficulty, from behind. A peg of wood is fixed into the axis, so as to prevent its effecting more than half a revolution. The widest part of the crescentic opening in the plate is sufficient to admit all the rays of the lantern before which it happens to be placed. On the plate being slowly turned half round, by means of the handle behind, the opening narrows until it is altogether lost in one of the horns of the crescent. The light of that lantern is gradually cut off as the aperture diminishes, until it is at length wholly shaded under the moveable cover occupying the interval between the horns of this crescentic opening. In proportion as the light is cut off from one, it is let on from the other tube, in consequence of the gradually increasing size of the crescent revolving before it, until at length the widest part of this opening in the plate is presented before the tube of the second lantern, the first being, as we have seen, shaded. This movement being reversed, the light is cut off from the second lantern, and again let on from the first, and so on alternately. Thus while the screen always presents the same circle of light, yet it is derived first from one lantern, then from the next.

When in use a slider is introduced into each lantern. The lantern before the mouth of which the widest part of the opening in the plate is placed, exhibits the painting on the screen, the light of the other lantern being then hid behind the cover. On turning the handle, this picture gradually becomes shaded, while the light from the second lantern streams through the widening opening. The effect on the screen is the melting away of the first picture, and the brilliant development of the second, the screen being at no instant left unoccupied by a picture.

The principle involved in this apparently complex, but in reality simple mechanism, is, merely the obscuration of one picture, and the throwing of a second in the same place on the screen. And it may be accomplished in a great variety of ways. Thus by simply placing a flat piece of wood, somewhat like the letter Z on a point in the centre, so that alternately one or the other of the pieces at the end should be raised or depressed before the lanterns, a dissolving scene is produced. Or, by fixing a moveable upright shade, which can be pushed alternately before one or the other of the lanterns, the same effect is produced.

Individuals exist in this metropolis whose sole occupation consists in painting the minute scenes or slides used for the phantasmagoria lanterns. The perfection to which these paintings are brought is surprising. There are two methods by which the sliders now employed are produced. In one of these, the outline and detail are entirely the work of the artist's pencil. For pictures representing landscapes, or wherever a spirited painting is required, this is the exclusive method employed. The colours are rendered transparent by being ground in Canada balsam and mixed with varnish. The other method is a transfer process. The outlines of the subject are engraved on copper plates, and the impression is received from these on thin sheets of glue, and is then transferred to a plate of glass, the impression being burnt in the same manner as is effected in earthenware. Sliders produced in this way receive the distinctive name of copper plate sliders. The subject is merely represented in outline, it being left to the artist to fill up with the necessary tints, &c. The advantages of this method for the production of paintings of a limited kind are obvious. Latterly photography on glass has been employed to obtain pictures for the magic lantern.

PHARMACEUTICAL PRODUCTS.—*Hops*. These hops are samples of the varieties in most estimation for the purposes of the brewer. The Goldings take their name from that of a grower who first introduced them; they are considered to be the finest, richest and most valuable in the market, varying, however, according to the soil in which they are grown and the treatment they receive; Jones's are of shorter growth than the others, and are thus useful by enabling the grower to make use of the poles which would be too short for the *Golding* or other varieties. *Colegates* are hardy but backward at harvest, running much to vine and capable of growing in comparatively poor soils.

These qualities are, however, of advantage, as the inferior soils may thus be beneficially occupied by them, and their harvest takes place after the finer sorts are all in. The grape hop takes its name from its habit of growing in clusters like the grape. It is hardy, not so particular as to soil as the Goldings, and is generally very productive in yield.

Some conception of the quantity of hops annually produced in Great Britain, principally in Kent, Sussex, Worcester, and Hereford, may be obtained from the fact that in 1842 the duty (2d. per lb.), amounted to 260,978*l.*: the plant belongs to the same natural family as hemp, *Cannabaceae*. Its botanical name is *Humulus lupulus*.

Pharmaceutical Extracts.—Pharmaceutical extracts were for a considerable period the most fallacious of all medical preparations. The high temperature to which they were subjected in the manufacture destroyed the active principle sought to be concentrated. Of late they have been prepared in some instances, by evaporation in the cold, a current of air being driven over the surface of the liquid. They are also safely obtainable by using an apparatus similar to that employed in the sugar manufacture.

Kouasso; a new remedial agent, for the removal of tape worm. That it is destructive to that parasitic disease has been satisfactorily shown. The plant has been long known in the East, and actively employed in Abyssinia. Dr. Pereira has given an elaborate account of this plant, which is known by the name of *Brayera anthelmintica*, from its properties and the name of its discoverer, Dr. Brayer. Wittstein and Martin have given chemical analyses of the plant.

Superphosphate of iron; a new preparation of iron recently introduced by Dr. Routh, supposed to be the same salt contained in the blood. It is free from all ferruginous taste, and so well adapted for children: believed to be more speedy in its action than the other salts of iron in cases of nervous debility, where there is a large quantity of phosphates voided by the urine, probably because it supplies directly to the brain the phosphorus, on the undue diminution of which the nervous derangement depends. Syrup of superphosphate of iron, adapted for administering the remedy to children, and probably the best form for general use.

PHOSPHORIC ACID, is the acid formed by the vivid combustion of phosphorus. In the British portion of the Exhibition, there was one acid missing which existed in great abundance and perfection amongst the German chemical preparations. We allude to the glacial phosphoric acid, of which that displayed by the Royal Prussian chemical manufactory at Schönebeck can scarcely be too highly spoken of. From some unknown cause, this has not attracted the attention which it deserves in the arts and manufactures of this country. For many of the wants of the dyer, the calico printer, the enameller, and even in the purification of some oils and fat, the glacial phosphoric acid has much to recommend it over any of the common acids at present in use. Nor need its price prove an insuperable obstacle to its introduction as a practical agent. Finely ground bone-ash, digested with a due proportion of oxalic acid and water, readily yields a solution of phosphoric acid, which requires only to be evaporated in a proper vessel to furnish at once this useful article. Unlike sulphuric and other strong acids, it is not decomposed by organic matter; and might hence be employed with great advantage in the precipitation of carmine and other delicate vegetable colours, as well as for more general purposes. Some experiments have also shown that combined with alumina and a little boracic acid, it is capable of producing a glaze for earthenware of extreme beauty and durability, in addition to its perfectly innocuous character and power of improving the colours imparted by most metallic oxides when applied to earthenware.

PHOSPHORUS. This interesting simple combustible, being an object of extensive consumption, and therefore of a considerable chemical manufacture, I shall describe the requisite manipulations for preparing it at some detail. Put 1 cwt. of finely ground bone-ash, such as is used by the assayers, into a stout tub, and let one person work it into a thin pap with twice its weight of water, and let him continue to stir it constantly with a wooden bar, while another person pours into it, in a uniform but very slender stream, 78 pounds of concentrated sulphuric acid.

The heat thus excited in the dilution of the acid, and in its reaction upon the calcareous base, is favorable to the decomposition of the bone phosphate. Should the resulting sulphate of lime become lumpy, it must be reduced into a uniform paste, by the addition of a little water from time to time. This mixture must be made out of doors, as under an open shed, on account of the carbonic acid and other offensive gases which are extricated. At the end of 24 hours, the pap may be thinned with water, and, if convenient, heated, with careful stirring, to complete the chemical change, in a square pan made of sheet lead, simply folded up at the sides. Whenever the paste has lost its granular character, it is ready for transfer into a series of tall casks, to be further diluted and settled, whereby the clear superphosphate of lime may be run off by a syphon from

the deposite of gypsum. More water must then be mixed with the precipitate, after subsidence of which, the supernatant liquor is again to be drawn off. The skilful operator employs the weak acid from one cask to wash the deposite in another, and thereby saves fuel in evaporation.

The collected liquors being put into a leaden, or preferably a copper pan, of proper dimensions, are to be concentrated by steady ebullition, till the calcareous deposite becomes considerable; after the whole has been allowed to cool, the clear liquor is to be run off, the sediment removed, and thrown on a filter. The evaporation of the clear liquor is to be urged till it acquires the consistence of honey. Being now weighed, it should amount to 37 pounds. One fourth of its weight of charcoal in fine powder, that is, about 9 pounds, are then to be incorporated with it, and the mixture is to be evaporated to dryness in a cast-iron pot. A good deal of sulphurous acid is disengaged along with the steam at first, from the reaction of the sulphuric acid upon the charcoal, and afterwards some sulphureted hydrogen. When the mixture has become perfectly dry, as shown by the redness of the bottom of the pot, it is to be allowed to cool, and packed tight into stoneware jars fitted with close covers, till it is to be subjected to distillation. For this purpose, earthen retorts of the best quality, and free from air-holes, must be taken, and evenly luted over their surface with a compost of fire-clay and horse-dung. When the coating is dry and sound, the retort is to be two thirds filled with the powder, and placed upon proper supports in the laboratory of an air-furnace, having its fire placed not immediately beneath the retort, but to one side, after the plan of a reverberatory; whereby the flame may play uniformly round the retort, and the fuel may be supplied as it is wanted, without admitting cold air to endanger its cracking. The gallery furnace of the palatinate (under *Mercury*) will show how several retorts may be operated upon together, with one fire.

To the beak of the retort properly inclined, the one end of a bent copper tube is to be tightly luted, while the other end is plunged not more than one quarter of an inch beneath the surface of water contained in a small copper or tin trough placed beneath, close to the side of the furnace, or in a wide-mouthed bottle. It is of advantage to let the water be somewhat warm, in order to prevent the concretion of the phosphorus in the copper tube, and the consequent obstruction of the passage. Should the beak of the retort appear to get filled with solid phosphorus, a bent rod of iron may be heated, and passed up the copper tube, without removing its end from the water. The heat of the furnace should be most slowly raised at first, but afterwards equally maintained in a state of bright ignition. After 3 or 4 hours of steady firing, carbonic acid and sulphurous acid gases are evolved in considerable abundance, provided the materials had not been well dried in the iron pot; then sulphureted hydrogen makes its appearance, and next phosphureted hydrogen, which last should continue during the whole of the distillation.

The firing should be regulated by the escape of this remarkable gas, which ought to be at the rate of about 2 bubbles per second. If the discharge comes to be interrupted, it is to be ascribed either to the temperature being too low, or to the retort getting cracked; and if upon raising the heat sufficiently no bubbles appear, it is a proof that the apparatus has become defective, and that it is needless to continue the operation. In fact, the great nicety in distilling phosphorus lies in the management of the fire, which must be incessantly watched, and fed by the successive introduction of fuel, consisting of coke with a mixture of dry wood and coal.

We may infer that the process approaches its conclusion by the increasing slowness with which gas is disengaged under a powerful heat; and when it ceases to come over, we may cease firing, taking care to prevent reflux of water into the retort, from condensation of its gaseous contents, by admitting air into it through a recurved glass tube, or through the lute of the copper adopter.

The usual period of the operation upon the great scale is from 24 to 30 hours. Its theory is very obvious. The charcoal at an elevated temperature disoxygenates the phosphoric acid with the production of carbonic acid gas at first, and afterwards carbonic oxide gas, along with sulphureted, carbureted, and phosphureted hydrogen, from the reaction of the water present in the charcoal upon the other ingredients.

The phosphorus falls down in drops, like melted wax, and concretes at the bottom of the water in the receiver. It requires to be purified by squeezing in a shamoy leather bag, while immersed under the surface of warm water, contained in an earthen pan. Each bag must be firmly tied into a ball form, of the size of the fist, and compressed, under the water heated to 130°, by a pair of flat wooden pincers, like those with which oranges are squeezed.

The purified phosphorus is moulded for sale into little cylinders, by melting it at the bottom of a deep jar filled with water, then plunging the wider end of a slightly tapering but straight glass tube into the water, sucking this up to the top of the glass, so as to warm

it, next immersing the end in the liquid phosphorus, and sucking it up to any desired height.

The tube being now shut at bottom by the application of the point of the left index, may be taken from the mouth and transferred into a pan of cold water to congeal the phosphorus; which then will commonly fall out of itself, if the tube be nicely tapered, or may at any rate be pushed out with a stiff wire. Were the glass tube not duly warmed before sucking up the phosphorus, this would be apt to congeal at the sides, before the middle be filled, and thus form hollow cylinders, very troublesome and even dangerous to the makers of phosphoric match-bottles. The moulded sticks of phosphorus are finally to be cut with scissors under water to the requisite lengths, and put up in vials of a proper size; which should be filled up with water, closed with ground stoppers, and kept in a dark place. For carriage to a distance, each vial should be wrapped in paper, and fitted into a tin-plate case.

Phosphorus has a pale yellow color, is nearly transparent, brittle when cold, soft and pliable, like wax, at the temperature of 70° F., crystallizing in rhombo-dodecahedrons out of its combination with sulphur, and of specific gravity 1.77. It exhales white fumes in the air, which have a garlic smell, appear luminous in the dark, and spontaneously condense into liquid phosphorous acid. Phosphorus melts in close vessels, at 95° F., into an oily-looking colorless fluid, begins to evaporate at 217.5° , boils at 554° , and if poured in the liquid state into ice-cold water, it becomes black, but resumes its former color when again melted and slowly cooled. It has an acrid disagreeable taste, and acts deleteriously in the stomach, though it has been administered as a medicine by some of the poison-doctors of the present day. It takes fire in the open air at the temperature of 165° , but at a lower degree if partially oxydized, and burns with great vehemence and splendor.

Inflammable match-boxes (*briquets phosphoriques*) are usually prepared by putting into a small vial of glass or lead a bit of phosphorus, and oxydizing it slightly by stirring it round with a redhot iron wire. The vial should be unstoppered only at the instant of plunging into it the tip of the sulphur match which we wish to kindle. Bendix has given the following recipe for charging such match-vials. Take one part of fine dry cork raspings, one part of yellow wax, eight parts of petroleum, and four of phosphorus, incorporate them by fusion, and when the mixture has congealed by cooling, it is capable of kindling a sulphur match dipped into it. Phosphorus dissolves in fat oils, forming a solution luminous in the dark at ordinary temperatures. A vial half filled with this oil, being shaken and suddenly uncorked, will give light enough to see the dial of a watch by night.

There are five combinations of phosphorus and oxygen:—1. the white oxyde; 2. the red oxyde; 3. hypophosphorous acid; 4. phosphorous acid; 5. phosphoric acid. The last is the only one of interest in the arts. It may be obtained from the sirupy superphosphate of lime above described, by diluting it with water, saturating with carbonate of ammonia; evaporating, crystallizing, and gently igniting the salt in a retort. The ammonia is volatilized, and may be condensed into water by a Woulfe's apparatus, while the phosphoric acid remains in the bottom of the retort. Phosphoric acid may be more readily produced by burning successive bits of phosphorus in a silver saucer, under a great bell jar inverted upon a glass plate, so as to admit a little air to carry on the combustion. The acid is obtained in a fine white snowy deposit; consisting, in this its dry state, of 44 of phosphorus and 56 of oxygen. That obtained from the sirupy solution is a hydrate, and contains 9.44 per cent. of water. If the atom of phosphorus be called 32 upon the hydrogen radix, then 5 atoms of oxygen = 40 will be associated with it in the dry acid, = 72; and an additional atom of water = 9, in the hydrate, will make its prime equivalent 81. Phosphorous acid seems to contain no more than 3 atoms of oxygen.

The only salts of this acid much in demand, are the phosphate of soda, and the ammonia phosphate of soda. The former is prepared by slightly supersaturating superphosphate of lime with crystals of carbonate of soda; warming the solution, filtering, evaporating, and crystallizing. It is an excellent purgative, and not unpalatable. The triple phosphate is used in docimastic operations; and is described under METALLURGY.

PHOSPHORUS AMORPHOUS. Amorphous phosphorus was discovered by Dr. Schrötter, of Vienna. It is identical in composition with ordinary phosphorus, and may be reconverted into it without loss of weight, and that merely by a change of temperature. This substance remains unaltered in the atmosphere, is insoluble in sulphuret of carbon, in alcohol, ether, and naphtha. It requires a heat of 260° C. to restore it to the crystalline state, and it is only at that heat that it begins to take fire in the open air. It is not luminous in the dark at any ordinary temperature. The apparatus for making it consists of a double iron pan; the intermediate space between the two contains a metallic bath of an alloy of tin and lead; with a cast-iron cover to the inner vessel, fitted to the top end by means of a screw, and fastened to the outer vessel by screw pins. In the

interior iron vessel, a glass vessel is fitted, in which the phosphorus to be operated upon is placed. From this inner vessel a tube passes, and is dipped into water to serve as a safety valve. A spirit lamp is applied under that pipe if necessary, to prevent it being clogged with phosphorus. The phosphorus to be converted is first of all melted and then cooled under water, and dried as much as possible. A fire is now made under the other vessel, and the temperature raised to such a degree as to drive off the air, &c. The temperature is to be gradually raised, until bubbles escape at the end of the pipe, which take fire as they enter the air, and the heat may soon rise in the bath till it be 500° Fahr. This temperature must be maintained for a certain time to be determined by experience: the apparatus may then be allowed to cool. The converted phosphorus is difficult to detach from the glass. It is to be levigated under water, and then drained in a bag. The phosphorus when moist should be spread thinly on separate shallow trays of sheet iron or lead, so placed alongside each other as to receive the heat of steam, and lastly of chloride of calcium or of sand, till the phosphorus, having been frequently stirred, shows no more luminous vapour. The operator should have water at hand to quench any fire that might arise. It is then to be washed till the water shows no trace of acid. Should the resulting phosphorus contain some of the unconverted article, this may be removed by bisulphuret of carbon. Thus, heat alone affects the transmutation.

Phosphorus and its Matches. Professor Schrötter's discovery of amorphous phosphorus has not hitherto led to any practical application towards diminishing the noxiousness of the manufacture of lucifer matches; though this curious substance may now be had at a moderate price from Messrs. Sturge of Birmingham. At Dixon's manufactory, Newton Heath, near Manchester, piles of timber are stored up ready for use; it is rapidly reduced into blocks of proper length, and next into tiny sticks, by machinery. These are tied up in bundles of about 8 inches in diameter, and carried into the sulphuring room, where they are dipped in the melted brimstone contained in an iron pot resting over a moderate fire. Each bundle is turned round and pressed, to prevent the cohesion of the sticks composing it.

They are now transferred to the phosphorus apartment, where they are dipped into a composition of chlorate of potash, phosphorus and glue, spread in a thin layer on a slab of stone or marble heated beneath by steam or hot water. The bundles are for this purpose arranged in frames about 2 feet long and 1 broad; but not in contact with each other. The operator holds the frame lengthwise, and dips the ends of the matches in the composition, taking care that all of them are coated. They are now sorted in a separate room, and put into boxes. Each box of lucifer matches, price retail one half-penny, passes through the hands of 17 persons, chiefly children, who earn by piece work from 3s. to 5s. per week; while the adults earn from 9s. to 12s.

The peculiar and most remarkable disease to which the workers in such a factory are subject is described in the Dublin Quarterly Journal of Science for August, 1851, by Mr. Harrison.

The first symptom is toothache, while the jaw is getting into a carious state, and the disease silently creeps on, until the sufferer becomes a loathsome object, or dies, becoming unable to open his jaws, of which the bones are being necrosed. Dreadful mutilations ensue, from the necessary surgical operations; causing the loss of the greater portion of the lower jaw. There are at this time in the factory several persons who have suffered severely. In the Museum of the Manchester Infirmary is the lower jaw of a young woman who is now at work. In some cases the bone in its diseased state has a spongy cellular appearance, with excrescences of a similar character adhering to it. The teeth generally continue sound and white, while the jaw that contains them is altered in texture and apparently dead. Loss of the greater part or whole of the lower jaw, is a frequent result. The cause, and cure, or prevention of this horrible new disease are still to be discovered.

Phosphorus paste for the destruction of rats and mice. The Prussian government issued an ordonnance on the 27th April, 1843, directing the following composition to be substituted for arsenic, for destroying rats and mice; enjoining the authorities of the different provinces to communicate, at the expiration of a year, the results of the trials made with it, with the view of framing a law on this subject.

The following is the formula for this paste:—

Take of phosphorus 8 parts, liquefy it in 180 parts of lukewarm water, pour the whole into a mortar, add immediately 180 parts of rye meal; when cold mix in 100 parts of butter melted, and 125 parts of sugar.

If the phosphorus is in a finely divided state, the ingredients may be all mixed at once, without melting them.

This mixture will retain its efficacy for many years, for the phosphorus is preserved by the butter, and only becomes oxidized on the surface.

Rats and mice eat this mixture with avidity; after which they swell out and soon die.

M. Simon has employed this mixture for many years, with constant success, by placing it in places frequented by these animals. According to him, the phosphorus is less dangerous than arsenic, for supposing the mixture to be badly made, and the phosphorus imperfectly divided, the oxidation which would take place in a few days would render it nearly inactive; and it would be almost impossible to employ it for the intentional poisoning of human beings.

PHOTOGRAPHY is the art of making pictorial impressions of objects by the action of light upon paper, &c., prepared with certain substances, and exposed to the sun or in the focus of a camera obscura to the image of the object to be represented; which impressions are then fixed by other chemical re-agents. Photographic paper may be made by dipping Whatman's glazed post paper into brine containing 90 grains of common salt dissolved in an ounce of water, wiping it with a towel, brushing over one side of it with a broad camel-hair brush, a solution of nitrate of silver, containing 50 grains to the ounce of distilled water, and drying it in the dark. The paper may be rendered more sensitive by repeating the above operation; drying it between each step. It affords perfect images of leaves and petals laid upon it, and exposed simply to the sunbeams. A solution of 100 grains of bromide of potassium in an ounce of distilled water answers still better than brine. The paper, when dry, is to be brushed over on one side with a solution containing 100 grains of nitrate of silver to an ounce of water; the paper being brushed, and dried in the dark. If the application of the nitrate of silver be repeated, it will render the paper more sensitive. The silvered side should be marked. This paper laid flat under painted glass, lace, leaves, feathers, ferns, &c., and exposed to the light of day, takes the impression of the objects. It is to be then washed with lukewarm water, and finally dipped in a solution containing one ounce of hyposulphite of soda, in about a pint of distilled water. The design of the object is necessarily reversed: the light parts forming the dark shades of the photogenic impression, and the dark parts the lighter ones. But a direct picture may be obtained by applying that paper, rendered transparent with white wax (see *CALOTYPE*), upon a sheet of white photogenic paper, and exposing it to the sunbeams, or bright daylight.

A modification of Photography, called *Chrysotype* by its inventor, Sir John Herschel, consists in washing the paper in a solution of ammonia-citrate of iron, drying it, and brushing it over with a solution of *ferro-sesquicyanure* of potassium. This paper, when dried in a perfectly dark room, is ready for use, the image being finally brought out by a neutral solution of silver.

Another modification by Sir John, called *Cyanotype*, is as follows: Brush the paper with the solution of the ammonia-citrate of iron, so strong as to resemble sherry-wine in color; expose the paper in the usual way, and pass over it very sparingly and evenly a wash made by dissolving common ferro-cyanide of potassium. As soon as this liquid is applied, the negative picture vanishes, and is replaced by the positive one, of a violet blue color, on a greenish yellow ground, which at a certain time possesses a high degree of sharpness, and singular beauty of tint.

The improved process of photography recently contrived by Mr. Robert Hunt is performed by washing over good letter-paper with the following liquid:—

A saturated solution of succinic acid	-	-	-	2 drams.
Mucilage of gum arabic	-	-	-	$\frac{1}{2}$ do.
Water	-	-	-	$1\frac{1}{2}$ do.

When the paper is dry, it is washed over once with a solution containing 1 dram of nitrate of silver in 1 ounce of distilled water. The paper is allowed to dry in the dark, and it is fit for use. It can be preserved in a portfolio, and employed at any time in the camera obscura, exposing it to the light from 2 to 8 minutes, according to its vivacity. When the paper is taken out of the camera, no trace of a picture can be seen. To produce this effect, mix 1 dram of a saturated solution of sulphate of iron, with 2 or 3 drams of mucilage of gum arabic, and brush over the paper evenly with this mixture. In a few seconds the latent images are seen to develop themselves, producing a negative photographic picture. The excess of the iron solution is to be washed off with a sponge whenever the best effect appears. The drawing is then to be soaked a short time in water, and is fixed by washing over with ammonia, or preferably with hyposulphite of soda; taking care to wash out the excess of salt. From the pictures thus produced, any number of others, corrected in light and shadow, may be produced by using like succinated papers, in the common way of transfer in sunshine. See also *CALOTYPE*, *DAGUERREOTYPE* and *HELIOGRAPHY*.

William Henry Fox Talbot, Esq., Lacock Abbey, Chippenham, has obtained a patent for improvements in photography. Patent dated June 12th, 1851.

The first part of this invention consists in obtaining photographic images on plates of glass prepared by the following means:—A plate of glass should be selected having

a smooth and well polished surface; and in order to obtain a photographic picture, the operator proceeds as follows:

1. Takes albumen or white of egg, and mixes the most liquid portions thereof (rejecting the rest) with an equal quantity of water, and having spread the mixture smoothly and evenly over the surface of the glass, allows it to dry spontaneously, or dries it at a fire.

2. He mixes an aqueous solution of nitrate of silver with a large proportion of alcohol, so that the mixture shall contain about 3 grains of the nitrate to each ounce of liquid. (This proportion may be varied from 1 to 6 grains in the ounce of liquid: but 3 grains is considered to be the best proportion.)

3. He dips the prepared plate for a few seconds into this mixture, then withdraws and dries it by a gentle heat, or allows it to dry spontaneously.

4. He dips the plate into distilled water, to remove any superfluous nitrate of silver.

5. He applies a second coating of albumen, in the same way as above directed, and dries the plate by the application of gentle heat, avoiding the use of too much heat, by which the nitrate of silver might be decomposed.

6. He takes an aqueous solution of protiodide of iron, containing 140 grains of protiodide to the ounce of water. A small quantity of free iodine in the solution, by which its colour would be rendered slightly yellow, will be found to be of advantage. To one measure of the solution, he adds one of acetic acid and ten of alcohol, and allows the mixture to stand for a few days previous to use.

7. He dips the plate into the solution, or allows the liquid to pass over the whole of its surface in a continuous stream. It is then dried, when it should be of a pale yellow colour, very clear, and uniformly transparent; and this completes the preparation of the plates. All the preceding operations may be performed in moderate daylight, but avoiding exposure to too strong a light, or to sunshine.

8. When it is desired to obtain a photographic picture, the operator takes a solution of nitrate of silver containing 100 grains of nitrate of silver to an ounce of water, and, having mixed two measures of the same with two of acetic acid and one of water he dips the albumenized plate therein once or twice, for a few seconds each time (performing the operation in a darkened room or by candlelight), for the purpose of rendering it sensitive. If the weather is cold, the plate should be slightly warmed before so dipping it. He then removes it to the camera without loss of time, as the plate ought to be used a few minutes after taking it out of the solution; and when a sufficiently strong photographic image is supposed to be obtained, the plate is transferred from the camera to the dark chamber or operating room.

9. It is then immersed in a solution of sulphate of iron, composed by mixing one measure of a saturated solution thereof in water with two measures of water (but the solution may be stronger or weaker, at the discretion of the operator,) by which the previously invisible images will be rapidly rendered perceptible.

10. The plate is then washed, and dipped in a rather strong solution of hyposulphite of soda in water, which, generally, in about a minute renders every part of the image more distinct and visible. The picture is then washed in distilled water, and the surface of the plate may be cleansed from any particles of dust, or other impurities, by rubbing it gently with cotton dipped in water; and if the above-described operations have been properly performed, the surface of the plate will not be at all injured by this cleaning. The picture is then dried, and the operation is finished. For the purpose of better preserving the picture, the plate may be covered with a coating of albumen or fine transparent varnish.

Although throughout the above processes certain proportions of chemical substances have been named, they may be varied very considerably, as is also the case in photographic operations generally.

The images obtained by this improved method, Mr. Talbot calls "Amphitypes," because they appear either positive or negative, according to the circumstances of light under which they are viewed. Thus, if held against a bright light, or against a sheet of white paper, they appear negative, and the reverse when held against a black surface and seen in obliquely reflected light. It is in the power of the operator, by varying the proportions of the chemicals employed, to obtain at pleasure positive images more or less distinct in comparison with the negative images; when it is intended to copy the image upon paper, it is desirable to obtain as strong a negative as possible on the glass plate, which is then copied on the paper, to produce thereon a positive image in the usual manner; but when the operator wishes to have a picture on the glass, he should endeavour to obtain a strong positive image. When this is obtained to his satisfaction, it may be preserved from injury and from contact with the air, by pouring black paint over the pictured side of the plate, and then by turning the glass the picture will be seen correctly, and not reversed as regards the right and left sides. This method of blacking one side of the plate is not, however, any part of the present in

vention. Throughout the specification the words negative and positive are made use of in the senses in which they are generally employed by photographers, viz., a positive image is that in which the lights and shades of the object are represented by lights and shades in the photograph, and a negative image is that in which a reverse effect is produced.

The method of operating just described is that which Mr. Talbot recommends when the object is close at hand, and the operator is in the vicinity of a darkened room, to which he can retire for the purpose of rendering his plates sensitive; but under circumstances, where the object is at a distance, and when the operator is on a journey or otherwise removed from any house or place where such conveniences exist, the following method of procedure may be adopted:—The operator constructs a glass cell with equal and parallel sides, open at the top and closed at the bottom and sides, and quite watertight, of a size just sufficient to receive one of the photographic plates, but not much greater, in order that there may be no waste of the chemicals employed. The posterior glass of the cell has one of its sides ground or unpolished, and the cell, when in use, is placed at the hinder part of the camera, so that when directed towards an object, the unpolished or ground surface may answer the purpose of the sheet of ground glass introduced in cameras to place the objects in their true focus. Allowance must, of course, be made for the unusual position occupied by the ground glass in this case. The top of the cell is provided at one corner with a funnel for the introduction of liquid, and the bottom is furnished with a stopcock and waste pipe terminating in a caoutchouc tube, which may be moved by hand from one to the other of two vessels which are provided to receive the used liquors escaping from the camera: the nitrate of silver solution is too expensive to be wasted, but the other ingredients, when once used, may be thrown away. These preparations made, the operator pours into the cell a quantity of liquid sufficient to fill it nearly full when it contains one of the photographic plates, and notes the quantity required. He then provides four bottles of that capacity, one of which he fills with solution of nitrate of silver, prepared as before directed under operation 8.; the second bottle is to contain a solution of sulphate of iron, as directed under operation 9.; the third bottle is filled with water, and the fourth with a strong solution of hyposulphite of soda. These quantities are sufficient for obtaining a single photographic picture, and when they are used, the bottles must be filled again. Having prepared a number of glass plates by means of processes before described, up to No. 7. inclusive, they are to be packed in a box ready for use: the operator, when he desires to obtain a photographic picture of an object, takes one of the plates from the box (which he can do without injury to it, as the plates in this condition are not sensitive to light), and place it in the camera, the focus of which he adjusts to the object. He then closes the front lens or object glass, lowers a curtain over the camera box, leaving exposed only the funnel at the top (and care should be taken to guard against any light entering through this), and the waste pipe at the bottom of the cell, and pours into the cell, through the funnel, the contents of the first bottle (nitrate of silver solution), for the purpose of rendering the plate sensitive to light. He may then proceed in two different ways. That is, he may open the front lens, and obtain the image while the plate is immersed in the solution; or, before opening the front lens, he may allow the nitrate of silver solution to escape through the waste pipe, and he will then obtain an image on the plate while the liquid is adhering to its sides. In the latter case, or after allowing the solution to escape, if the former method is adopted, he closes the stopcock, and successively pours into the cell the contents of the second and third bottles, allowing each to remain in for about half a minute; and, finally, he pours in the hyposulphite of soda solution, after which the plate is removed, and the image being now fixed, and not liable to injury from exposure to air, the plate is washed and placed in a box to be finished and varnished when the day's operations are completed. Another method, but one which is less simple, is to use four bottles of larger size than those above described, but containing the same liquids. These bottles are placed on a stand above the camera, and from each of them descends a tube of India rubber furnished with two stopcocks, which are placed at such distances apart, that the interval of tube between them shall be of a capacity equal to that of the cell when it contains a plate. These tubes dip into a funnel which communicates by a suitable pipe with the funnel leading to the cell. The liquids are successfully supplied to the cell from the bottles, and the method of operating according to this system is the same as that just described. The images obtained on glass by these means may be copied on to paper, in the usual manner. In fixing the images on paper, it is recommended, after washing them, to immerse the paper in a hot solution of iodide of potassium before dipping in the solution of hyposulphite of soda; by which means a better fixation of the image will be obtained.

Under this branch of his invention, Mr. Talbot claims the mode of preparing the glass plates, especially the use of a weak solution of nitrate of silver, immediately after the first coating of albumen; also the conjoint use of protiodide of iron and sulphate of iron, upon albumenized glass plates; and also the simultaneous production upon glass plates

of images which are both positive and negative, according to the light in which they are viewed. (In the specification of a patent granted to Messrs. Malone and Talbot, 19th Dec. 1849, a method is described of producing such images, which differs from the present in the prior formation of the negative image, which is afterwards converted into a positive one.) Also the apparatus described to be used along with the camera enabling the operator to work without the necessity of darkening the apartment in which he works, or of employing a tent or other contrivance for working in the shade, when taking photographic pictures at a distance from any house. The form of the apparatus may be considerably varied, but the essential point is, that the glass plate is placed in the cell in a partly prepared state, in which it is insensible to light, and is not removed from the cell, until the photographic picture is finished, with the exception of the final washing and drying. The patentee does not claim as new the mere use of a glass cell containing nitrate of silver, into which the photographic plate is dropped previous to, or during the formation of the image; but he claims the addition of the stopcock and waste-pipe, and the general arrangements, which render unnecessary the removal of the plate from the cell before the picture is finished. He states, also, that he believes the arrangement of four vessels furnished with tubes and stopcocks for pouring measured quantities of different fluids into the glass cell to be a new one.

The second part of the invention consists of a method of obtaining, under certain circumstances, the photographic picture of objects which are in rapid motion. An electric battery of the greatest power which can be conveniently obtained, is arranged in a darkened room, and, supposing the moving body whose picture is required is a wheel revolving upon its axis, the camera is placed at a convenient distance from it, and adjusted so as to have the image of the object in its focus. A glass plate is then taken, which has been previously prepared, in the way described above, and it is rendered sensitive with nitrate of silver in the way also above described: it is then placed in the camera and the electric battery is discharged, producing a sudden flash of light, which illuminates the object; the image thus taken on the glass plate is then rendered visible, and the process finished, as before directed. If the process is properly conducted, a distinct positive image of the moving body will be seen upon the glass, the rapidity of the motion not affecting the accuracy of the delineation.

What is claimed under this head of the invention is the use of the instantaneous light of an electric battery in such a way as to obtain the photographic image of a body illuminated thereby.

PICAMARE, is a thick oil, one of the six new principles detected by M. Reichenbach in wood-tar. See CREOSOTE and PARAFFINE. Picamare constitutes 1-6th of beech-tar.

PICKLES are various kinds of vegetables and fruits preserved in vinegar. The substances are first well cleaned with water, then steeped for some time in brine, and afterward transferred to bottles, which are filled up with good vinegar. Certain fruits, like walnuts, require to be pickled with scalding-hot vinegar; others, as red cabbage, with cold vinegar; but onions, to preserve their whiteness, with distilled vinegar. Wood vinegar is never used by the principal pickle-manufacturers, but the best malt or white-wine vinegar, No. 22 or 24. Kitchener says, that by parboiling the pickles in brine, they will be ready in half the time of what they require when done cold. Cabbage, however, cauliflowers, and such articles, would thereby become flabby, and lose that crispness which many people relish. When removed from the brine, they should be cooled, drained, and even dried, before being put into the vinegar. To assist the preservation of pickles, a portion of salt is often added, and likewise, to give flavor, various spices, such as long pepper, black pepper, white pepper, allspice, ginger, cloves, mace, garlic, mustard, horseradish, shallots, capsicum. When the spices are bruised, they are most efficacious, but they are apt to render the pickle turbid and discolored. The flavoring ingredients of Indian pickle are Curry powder mixed with a large proportion of mustard and garlic. Green peaches are said to make the best imitation of the Indian mango.

I have examined the apparatus in the great fish-sauce, pickle, and preserved-fruit establishment of Messrs. Crosse and Blackwell, Soho square, and found it arranged on the principles most conducive to economy, cleanliness, and salubrity; no material employed there is ever allowed to come into contact with copper. A powerful steam-boiler is placed in one corner of the ground floor of the factory, from which a steam-pipe issues, and is laid horizontally along the wall about 4 feet above the floor. Under this pipe a range of casks is placed, into the side of each of which a branch steam-pipe, furnished with a stop-cock, is inserted, while the mouth of the cask is exactly closed with a pan of salt-glazed earthenware, capable of resisting the action of every acid, and incapable of communicating any taint to its contents. These casks form, by their non-conducting quality as to heat, the best kind of steam-jackets. In these pans the vinegars with their compounds are heated, and the fish and other sauces are prepared.

The waste steam at the farthest extremity of the pipe is conducted into a reservoir of clean water, so as to furnish a constant supply of hot water for washing bottles and utensils.

The confectionary and ham-smoking compartments are placed in a separate fireproof chamber on the same floor.

The floor above is occupied along the sides with a range of large rectangular cast iron cisterns, furnished with a series of steam-pipes, laid gridironwise along their bottoms, which pipes are covered with a perforated wooden shelf. These cisterns being filled up to a certain height above the shelf with water, the bottles full of green gooseberries, apricots, cherries, &c., to be preserved, are set upon the shelf, and the steam being then admitted into the gridiron pipes, the superjacent water gets gradually heated to the boiling point; the air in the bottles round the fruit is thus partly expelled by expansion, and partly disoxygenated by absorption of the green vegetable matter. In this state the bottles are tightly corked, and being subsequently sealed, preserve the fruit fresh for a very long period.

The sauces, pastes, and potted meats, prepared in the above-described apparatus, can seldom be rivalled and probably not surpassed in the kitchens of the most fastidious gastronomes.

PICROMEL, is the name given by M. Thenard to a black bitter principle which he supposed to be peculiar to the bile. MM. Gmelin and Tiedemann have since called its identity in question.

PICROTOXINE, is an intensely bitter poisonous vegetable principle, extracted from the seeds of the *Menispermum cocculus*, (*Cocculus Indicus*.) It crystallizes in small white needles, or columns, dissolves in water and alcohol. It does not combine with acids, but with some bases, and is not therefore of an alkaline nature, as had been at first supposed.

PIGMENTS, VITRIFIABLE, belong to five different styles of work: 1. to enamel painting; 2. to painting on metals; 3. to painting on stoneware; 4. to painting on porcelain; 5. to stained glass. See VITRIFIABLE PIGMENTS.

PIGMENTS. 1. *White*. Alumina, white clay, heavy spar, chalk, gypsum, alabaster, and starch, and sulphate of lead.

2. *Blues*. Lapis lazuli blue; azure blue; artificial ultramarine; Thenard's blue or cobaltic; Giessen blue is Prussian blue dissolved in oxalic acid.

Copper blue, or hydrated oxide of copper, called mountain blue; indigo; litmus blue; blue (violet) from logwood by salt of tin and alkalis.

3. *Green*. Bremer; hydrated oxide of copper by decomposing a salt of copper with alkali; Brunswick and mountain green are arsenites of copper, acetate of copper or verdigris; Scheele's green; mixtures of chrome yellow and Prussian blue; oxide of chrome as an enamel colour; green earth, silicate and phosphate of the protoxide of iron; vegetable green, an extract of buckthorn berries, called also sap-green.

4. *Yellow*. Chrome; yellow antimonite of lead or Naples yellow, orpiment; hydrated oxide of iron; yellow ochre or Sienna yellow; gamboge; turmeric; yellow wood or fustic; quercitron; weld; yellow berries; saffron; annatto.

Red pigments. Cinnabar; basic chromate of lead; red lead; oxide of iron; red lake dyes; carmine; cochineal; kermes; Brazil wood; madder and its lake; lac lake; alkanet root; sandal wood; safflower; umber, or earthy clay ironstone; Cologne umber; earthy brown coal, lamp black, and Frankfort vine black; bone black; sepia, obtained by drying the black fluid of the cuttle-fish, extracted by means of caustic lye; catechu; dyes with mordants.

PIMENTO (*Myrtus pimenta*, or Jamaica pepper) consists, according to Bonastre's complicated analysis, of—

	Shells or capsules.	Kernels.

PINCHBECH, is a modification of brass; see that article and COPPER.

PINE-APPLE YARN and CLOTH. In Mr. Zincke's process, patented in December, 1836, for preparing the filaments of this plant, the *Bromelia ananas*, the leaves being plucked, and deprived of the prickles round their edges by a cutting instrument, are then beaten upon a wooden block with a wooden mallet, till a silky-looking mass of fibres be obtained, which are to be freed by washing from the green secula. The fibrous part must next be laid straight, and passed between wooden rollers. The leaves should be gathered between the time of their full maturity and the ripening of the fruit. If earlier or later, the fibres will not be so flexible, and will need to be cleared by a boil in soapy water for some hours; after being laid straight under the pressure of a wooden grating, to prevent their becoming entangled. When well washed and dried, with occasional shaking out, they will now appear of a silky fineness. They may be then spun into porous rovings, in which state they are most conveniently bleached by the ordinary methods.

Specimens of cambrie, both bleached and unbleached, woven with these fibres, have been recently exhibited, which excited hopes of their rivalling the finest flax fabrics, but in my opinion without good reason, on account of their want of strength.

PINEY TALLOW is a concrete fat obtained by boiling with water the fruit of the *Vateria indica*, a tree common upon the Malabar coast. It seems to be a substance intermediate between tallow and wax; partaking of the nature of stearine. It melts at $97\frac{1}{2}^{\circ}$ F., is white or yellowish, has a spec. grav. of 0.926; is saponified by alkalis, and forms excellent candles. Dr. Benjamin Babington, to whom we are indebted for all our knowledge of piney tallow, found its ultimate constituents to be, 77 of carbon, 12.3 of hydrogen, and 10.7 of oxygen.

PIN MANUFACTURE. (*Fabrique d'épingles*, Fr.; *Nadelfabrik*, Germ.) A pin is a small bit of wire, commonly brass, with a point at one end, and a spherical head at the other. In making this little article, there are no less than fourteen distinct operations.

1. *Straightening the wire.* The wire, as obtained from the drawing-frame, is wound about a bobbin or barrel, about 6 inches diameter, which gives it a curvature that must be removed. The straightening engine is formed by fixing 6 or 7 nails upright in a waving line on a board, so that the void space measured in a straight line between the first three nails may have exactly the thickness of the wire to be trimmed; and that the other nails may make the wire take a certain curve line, which must vary with its thickness. The workman pulls the wire with pincers through among these nails, to the length of about 30 feet, at a running draught; and after he cuts that off, he returns for as much more; he can thus finish 600 fathoms in the hour. He next cuts these long pieces into lengths of 3 or 4 pins. A day's work of one man amounts to 18 or 20 thousand dozen of pin-lengths.

2. *Pointing* is executed on two iron or steel grindstones, by two workmen, one of whom roughens down, and the other finishes. Thirty or forty of the pin wires are applied to the grindstone at once, arranged in one plane, between the two forefingers and thumbs of both hands, which dexterously give them a rotatory movement.

3. *Cutting these wires into pin-lengths.* This is done by an adjusted chisel. The intermediate portions are handed over to the pointer.

4. *Twisting of the wire for the pin-heads.* These are made of a much finer wire, coiled into a compact spiral, round a wire of the size of the pins, by means of a small lathe constructed for the purpose.

5. *Cutting the heads.* Two turns are dexterously cut off for each head, by a regulated chisel. A skilful workman may turn off 12,000 in the hour.

6. *Annealing the heads.* They are put into an iron ladle, made redhot over an open fire, and then thrown into cold water.

7. *Stamping or shaping the heads.* This is done by the blow of a small ram, raised by means of a pedal lever and a cord. The pin-heads are also fixed on by the same operative, who makes about 1500 pins in the hour, or from 12,000 to 15,000 per diem; exclusive of one thirteenth, which is always deducted for waste in this department, as well as in the rest of the manufacture. Cast heads, of an alloy of tin and antimony, were introduced by patent, but never came into general use.

8. *Yellowing or cleaning the pins* is effected by boiling them for half an hour in sour beer, wine lees, or solution of tartar; after which they are washed.

9. *Whitening or tinning.* A stratum of about 6 pounds of pins is laid in a copper pan, then a stratum of about 7 or 8 pounds of grain tin; and so alternately till the vessel be filled; a pipe being left inserted at one side, to permit the introduction of water slowly at the bottom, without deranging the contents. When the pipe is withdrawn, its space is filled up with grain tin. The vessel being now set on the fire, and the water becoming hot, its surface is sprinkled with 4 ounces of cream of tartar; after which it is allowed to boil for an hour. The pins and tin grains are, lastly, separated by a kind of cullender.

10. *Washing the pins* in pure water.

11. *Drying and polishing them*, in a leather sack filled with coarse bran, which is agitated to and fro by two men.

12. *Winnowing*, by fanners.

13. *Pricking the papers* for receiving the pins.

14. *Papering*, or fixing them in the paper. This is done by children, who acquire the habit of putting up 36,000 per day.

The pin manufacture is one of the greatest prodigies of the division of labor; it furnishes 12,000 articles for the sum of three shillings, which have required the united diligence of fourteen skilful operatives.

The above is an outline of the mode of manufacturing pins by hand labor, but several beautiful inventions have been employed to make them entirely or in a great measure by machinery; the consumption for home sale and export amounting to 15 millions daily, for this country alone. One of the most elaborate and apparently complete is that for which Mr. L. W. Wright obtained a patent in May, 1824. A detailed description of it will be found in the 9th volume of Newton's London Journal. The following outline will give my readers an idea of the structure of this ingenious machine:—

The rotation of a principal shaft, mounted with several cams, gives motion to various sliders, levers, and wheels, which work the different parts. A slider pushes pincers forwards, which draw wire from a reel, at every rotation of the shaft, and advance such a length of wire as will produce one pin. A die cuts off the said length of wire by the descent of its upper chap; the chap then opens a carrier, which takes the pin to the pointing apparatus. Here it is received by a holder, which turns round, while a bevel-edged file-wheel rapidly revolves, and tapers the end of the wire to a point. The pin is now conducted by a second carrier to a finer file-wheel, in order to finish the point by a second grinding. A third carrier then transfers the pin to the first heading die, and by the advance of a steel punch, the end of the pin wire is forced into a recess, whereby the head is partially swelled out. A fourth carrier removes the pin to a second die, where the heading is perfected. When the heading-bar retires, a forked lever draws the finished pin from the die, and drops it into a receptacle below.

I believe the chief objection to the raising of the heads by strong mechanical compression upon the pins, is the necessity of softening the wire previously; whereby the pins thus made, however beautiful to the eye, are deficient in that stiffness which is so essential to their employment in many operations of the toilet.

Edelsten, and Williams, New Hall Works, Birmingham, Manufacturers. Pins, the heads and shafts being formed of one solid piece of metal, in order to render the head immoveable and smooth in use, made by improved machinery. Model dies to show the formation of the head. Elastic hair-pins. Specimens of iron wire in various sizes. In pin making the wire is brass (a compound of copper and zinc): it is reduced by the ordinary process of wire drawing to the requisite thickness: in this process it is necessarily curved. To remove this it is re-wound, and pulled through between a number of pins arranged at the draw or straightening bench; it is then cut into convenient lengths for removal, and finally reduced to just such a length as will make two pins. The pointing is done upon steel mills (revolving wheels), the circumference of which is cut with teeth, the one fine, the other coarse. Thirty or forty lengths are packed up at once, and, as in needle-making, the cast of hand given by the workman makes them revolve, and the whole are pointed at once; the same operation is performed with the other end. The process of heading is next performed as follows: a number of the pointed wires now cut in two, are placed in the feeder of the machine; one drops, is firmly seized, and, by means of a pair of dies, a portion of the metal is forced up into a small bulb; by a beautifully simple and automatic arrangement, it is passed into another, when a small horizontal hammer gives it a sharp tap, which completes the head. The white colour is produced by boiling in a solution of cream of tartar and tin. They are then dried, and passed into the hands of the wrappers-up. The preparation or marking of the paper is peculiar, and is done by means of a moulded piece of wood, the moulds corresponding to those portions which represent the small folds of paper through which the pins are passed, and thereby held. The pins are then taken to the paperers, who are

each seated in front of a bench, to which is attached a horizontally hinged piece of iron the edge of which is notched with a corresponding number of marks to the number of pins to be struck; the small catch which holds together the two parts of the iron is released, the paper introduced, and a pin inserted at every mark; the paper is then released, and the task of examination follows, which is the work of a moment. The paper of pins is held so that the light strikes upon it: those defective are immediately detected by the shade, are taken out, and others substituted in their stead. An ancient edict of Henry VIII., held that, "no one should sell any pins but such as were double-headed, and the heads soldered fast on."

Pins, Improved.—The selection and preparation of the wire.—The iron or steel wire employed should be very round, and, to protect it from rust, it should at the last drawing be lubricated by means of a sponge saturated with oil, placed between the draw-plate and reel. In all the subsequent stages of the manufacture, care should also be taken to preserve the pins from oxidation by keeping them well oiled and greased.

The cleansing and polishing.—The wire being cut into pins, and these headed and pointed, all according to the usual methods, the pins are thrown into a revolving cylinder of wood containing a bath of soap and water in a hot state. It is of the capacity of about $9\frac{1}{2}$ gallons, but should not contain more than about $1\frac{1}{2}$ gallons of water, with about 2 ounces of soap dissolved therein, as this quantity will be sufficient for the treatment of about $18\frac{1}{2}$ lbs. weight of pins at a time. The cylinder, when thus charged, is made to revolve for about a quarter of an hour; at the expiration of which time the pins are found free from the oil with which they were previously coated, and also very much smoothed and polished by their rubbing one against the other.

The drying. The pins are next dried by transferring them to another cylinder partially filled with well dried sawdust (preferring for the purpose the sawdust of poplar wood), and causing this cylinder to revolve for about ten minutes; or, instead of employing a cylinder of this description, the pins may be thrown into a bag or bags partially filled with the sawdust, and the requisite friction produced by swinging or rolling these bags about for the same length of time.

The copper coating bath or mixture.—Into a glass or stone vase, the inventor puts about $1\frac{1}{2}$ gallons of soft water, seven-tenths of a pound of sulphuric acid, six-one hundredth lb. of salt of tin, eight-one hundredth lb. of crystallized sulphate of zinc, and 108 grs. of pure sulphate of copper, and leaves this mixture to work for about 24 hours, so that the salts and sulphates may be properly dissolved. This is found to be, on the whole, the mixture best adapted for the purpose in view; but most of the ingredients mentioned may have others substituted for them, as, for example, any other acid or substance producing like effects may be used instead of the sulphuric acid, or the sulphate of tin may be substituted for the salt of tin.

The copper coating process.—The mixture, prepared as last directed, is introduced into another revolving cylinder, and pins about $18\frac{1}{2}$ lbs. weight are thrown into the midst of it. The cylinder is then caused to revolve for about half an hour, which serves at once to remove any verdigris from the pins to impart a high polish to them, and to give a beginning to the copper coating process. At the end of the half hour or thereabouts 232 grs. of crystallized sulphate of copper in coarse powder, and 150 grs. of crystallized sulphate of zinc, previously dissolved in soft water, are added to the mixture in the cylinder, and the whole again agitated for about a quarter of an hour. The pins are by this operation not only completely coated, but acquire a very considerable degree of polish. The copper liquors being drawn off, the pins are washed with cold water in the rotating cylinder, and afterwards in a tub with soap and water out of contact with air, where they are well shaken. The contents of the tub are then emptied into a wooden strainer, having a perforated bottom of tin plate iron. The pins are finally dried by agitation with dry sawdust.

The tinning and blanching are performed by laying the pins upon plates of very thin tin placed one above another, in a tinned copper boiler containing a solution of about $\frac{4}{5}$ two-fifth lbs. of crude tartar or cream of tartar, in about 22 galls. of water, and then setting the whole to boil for about 12 hours. The tartar solution should be prepared at least 24 hours previously. A little more cream of tartar improves the brilliancy of the pins.

PIPERINE is a crystalline principle extracted from black pepper by means of alcohol. It is colorless, has hardly any taste, fuses at 212° F.; is insoluble in water, but soluble in acetic acid, ether, and most readily in alcohol.

PITCH, MINERAL, is the same as BITUMEN and ASPHALT.

PITCH of wood-tar (Poiz, Fr.; Pech, Germ.) is obtained by boiling tar in an open iron pot, or in a still, till the volatile matters be driven off. Pitch contains pyroligneous resin, along with colophony (common rosin), but its principal ingredient is the former, called by Berzelius pyretine. It is brittle in the cold, but softens and becomes ductile

with heat. It melts in boiling water, and dissolves in alcohol and oil of turpentine, as well as in carbonated or caustic alkaline leys. For PYRETINE, see the mode of preparing it from birch wood, for the purpose of preparing *Russia LEATHER*.

PITCOAL. (*Houille*, Fr.; *Steinkohle*, Germ.) This is by far the most valuable of mineral treasures, and the one which, at least in Great Britain, makes all the others available to the use and comfort of man. Hence it has been searched after with unremitting diligence, and worked with all the lights of science, and the resources of art.

The Brora coal-field in Sutherlandshire is the most remarkable example in this, or in perhaps any country hitherto investigated, of a pseudo coal-basin among the deeper secondary strata, but above the new sandstone or red marl formation. The Rev. Dr. Buckland and Mr. C. Lyell, after visiting it in 1824, had expressed an opinion that the strata there were wholly unconnected with the proper coal formation below the new red sandstone, and were in fact the equivalent of the oolitic series; an opinion fully confirmed by the subsequent researches of Mr. Murchison. (*Geol. Trans.* for 1827, p. 293.) The Brora coal-field forms a part of those secondary deposits which range along the south-east coast of Sutherlandshire, occupying a narrow tract of about twenty miles in length, and three in its greatest breadth.

One stratum of the Brora coal-pit is a coal-shale, composed of a reed-like striated plant of the natural order *Equisetum*, which seems to have contributed largely towards the formation of that variety of coal. From this coal-shale, the next transition upwards is into a purer bituminous substance approaching to jet, which constitutes the great bed of coal. This is from 3 feet 3 inches to 3 feet 5 inches thick, and is divided nearly in the middle by a thin layer of impure indurated shale charged with pyrites, which, if not carefully excluded from the mass, sometimes occasions spontaneous combustion upon exposure to the atmosphere; and so much, indeed, is that mineral disseminated throughout the district, that the shales might be generally termed "pyritiferous." Inattention on the part of the workmen, in 1817, in leaving a large quantity of this pyritous matter to accumulate in the pit, occasioned a spontaneous combustion, which was extinguished only by excluding the air; indeed, the coal-pit was closed in and remained unworked for four years. The fires broke out again in the pit in 1827.

The purer part of the Brora coal resembles common pitcoal; but its powder has the red ferruginous tinge of pulverized lignites. It may be considered one of the last links between lignite and true coal, approaching very nearly in character to jet, though less tenacious than that mineral; and, when burnt, exhaling but slightly the vegetable odor so peculiar to all imperfectly bituminized substances. The fossil remains of shells and plants prove the Brora coal to be analogous to that of the eastern moorlands of Yorkshire, although the extraordinary thickness of the former, compared with any similar deposit of the latter (which never exceeds from 12 to 17 inches), might have formerly led to the belief that it was a detached and anomalous deposit of true coal, rather than a lignite of any of the formations above the new red sandstone: such misconception might more easily arise in the infancy of geology, when the strata were not identified by their fossil organic remains.

On the coast of Yorkshire the strata of this pseudo coal formation appear in the following descending order, from Filey Bay to Whitby. 1. Coral-rag. 2. Calcareous grit. 3. Shale, with fossils of the Oxford clay. 4. Kelloway rock (swelling out into an important arenaceous formation). 5. Cornbrash. 6. Coaly grit of Smith. 7. Pierstone (according to Mr. Smith, the equivalent of the great oolite). 8. Sandstone and shale, with peculiar plants and various seams of coal. 9. A bed with fossils of the inferior oolite. 10. Marl-stone? 11. Alum-shale or lias. All the above strata are identified by abundant organic remains.

In the oolitic series, therefore, where the several strata are developed in conformity with the more ordinary type of these formations, we may venture to predict with certainty, that no carboniferous deposits of any great value will ever be discovered, at all events in Great Britain. A want of such knowledge has induced many persons to make trials for coal in beds subordinate to the English oolites, and even superior to them, in places where the type of formation did not offer the least warrant for such attempts.

The third great class of terrestrial strata, is the proper coal-measures, called the *carboniferous rocks*, our leading object here, and to which we shall presently return.

The transition rocks which lie beneath the coal-measures, and above the primitive rocks, or are anterior to the carboniferous order, and posterior to the primitive, contain a peculiar kind of coal, called anthracite or stone-coal, approaching closely in its nature to carbon. It is chiefly in the transition clay-slate that the anthracite occurs in considerable masses. There is one in the transition slate of the little Saint Bernard, near the village of *la Thuile* (in the Alps). It is 100 feet long, and 2 or 3 yards thick.

The coal burns with difficulty, and is used only for burning lime. There are several of the same kind in that country, which extend down the reverse slope of the mountains looking to Savoy. The slate enclosing them presents vegetable impressions of reeds or analogous plants. To the transition clay-slate we must likewise refer the beds of anthracite that M. Hericart de Thury observed at very great heights in the Alps of Dauphiny, in a formation of schist and gray-wacke with vegetable impressions, which reposes directly on the primitive rocks.

The great carboniferous formation may be subdivided into four orders of rocks: 1. the coal-measures, including their manifold alternations of coal-beds, sandstones, and shales; 2. the millstone grit and shale towards the bottom of the coal measures; 3. the carboniferous limestone, which projecting to considerable heights above the outcrop of the coal and grit, acquires the title of mountain limestone; 4. the old red sandstone, or connecting link with the transition and primary rock basin in which the coal system lies.

The coal-fields of England, from geographical position, naturally fall under the following arrangement:—1. *The great northern district*; including all the coal-fields north of Trent. 2. *The central district*; including Leicester, Warwick, Stafford, and Shropshire. 3. *The western district*; subdivided into *north-western*, including North Wales, and the *south-western*, including South Wales, Gloucester, and Somersetshire.

There are three principal coal-basins in Scotland: 1. that of Ayrshire; 2. that of Clydesdale; and 3. that of the valley of the Forth, which runs into the second in the line of the Union Canal. If two lines be drawn, one from Saint Andrews on the north-east coast, to Kilpatrick on the Clyde, and another from Aberlady, in Haddingtonshire, to a point a few miles south of Kirkoswald in Ayrshire, they will include between them the whole space where pitcoal has been discovered and worked in Scotland.

The great coal-series consists of a regular alternation of mineral strata deposited in a great concavity or basin, the sides and bottom of which are composed of transition rocks. This arrangement will be clearly understood by inspecting *fig. 1051* which represents a section of the coal-field south of Malmesbury.

Fog hill, N. of Lansdowne

1, 1, old red sandstone; 2, mountain limestone; 3, millstone grit; 4, 4, coal seams; 5, Pennant, or coarse sandstone; 6, new red sandstone, or red marl; 7, 7, lias; 8, 8, inferior oolite; 9, great oolite; 10, cornbrash and Forest marble.

No. 1, or the old red sandstone, may therefore be regarded as the characteristic lining of the coal basins; but this sandstone rests on transition limestone, and this limestone on gray-wacke. This methodical distribution of the carboniferous series is well exemplified in the coal-basin of the Forest of Dean in the south-west of England, and has been accurately described by Mr. Mushet.

The *gray-wacke* consists of highly inclined beds of slaty micaceous sandstone, which on the one hand alternates with and passes into a coarse breccia, having grains as large as peas; on the other, into a soft argillaceous slate. The gray-wacke stands bare on the north-eastern border of the Forest, near the southern extremity of the chain of transition limestone, which extends from Stoke Edith, near Hereford, to Flaxley on the Severn. It is traversed by a defile, through which the road from Gloucester to Ross winds. The abruptness of this pass gives it a wild and mountainous character, and affords the best opportunity of examining the varieties of the rock.

The *Transition limestone* consists in its *lower beds* of fine-grained, tender, extremely argillaceous slate, known in the district by the name of *water-stone*, in consequence of the wet soil that is found wherever it appears at the surface. Calcareous matter is interspersed in it but sparingly. Its *upper beds* consist of shale alternating with extensive beds of stratified limestone. The lowest of the calcareous strata are thin, and alternate with shale. On these repose thicker strata of more compact limestone, often of a dull blue color. The beds are often dolomitic, which is indicated by straw yellow color, or dark pink color, and by the sandy or glimmering aspect of the rock.

The *old red sandstone*, whose limits are so restricted in other parts of England, here

occupies an extensive area. The space which it covers, its great thickness, its high inclination, the abrupt character of the surface over which it prevails, and the consequent display of its strata in many natural sections, present in this district advantages for studying the formation, which are not to be met with elsewhere in South Britain. In the neighborhood of Mitchel Dean, the total thickness of this formation, interposed conformably between the transition and mountain limestone, is from 600 to 800 fathoms. The old red sandstone is characterized in its upper portion by the presence of silicious conglomerate, containing silicious pebbles, which is applied extensively to the fabrication of millstones near Monmouth, and on the banks of the Wye. This sandstone encircles the Forest with a ring of very elevated ground, whose long and lofty ridges on the eastern frontier overhang the valley of the Severn.

The *mountain limestone*, or carboniferous, is distinguished from transition limestone, rather by its position than by any very wide difference in its general character or organic remains. According to the measurements of Mr. Mushet, the total thickness of the mountain limestone is about 120 fathoms. The zone of limestone belonging to this coal-basin, is from a furlong to a mile in breadth on the surface of the ground, according as the dip of the strata is more or less rapid. The angle of dip on the northern and western border is often no more than 10° , but on the eastern it frequently amounts to 80° . The calcareous zone that defines the outer circle of the basin, suffers only one short interruption, scarcely three miles in length, where in consequence of a fault the limestone disappears, and the coal-measures are seen in contact with the old red sandstone.

Coal measures.—Their aggregate thickness amounts, according to Mr. Mushet, to about 500 fathoms. 1. The lowest beds, which repose on the mountain limestone, are about 40 fathoms thick, and consist here, as in the Bristol coal-basin, of a red silicious grit, alternating with conglomerate, used for millstones; and with clay, occasionally used for ochre. 2. These beds are succeeded by a series about 120 fathoms thick, in which a gray grit-stone predominates, alternating in the lower part with shale, and containing 6 seams of coal. The grits are of a fissile character, and are quarried extensively for flag-stone, ashlers, and fire-stone. 3. A bed of grit, 25 fathoms thick, quarried for hearth-stone, separates the preceding series from the following, or the 4th, which is about 115 fathoms thick, and consists of from 12 to 14 seams of coal alternating with shale. 5. To this succeeds a straw-colored sandstone, nearly 100 fathoms thick, forming a high ridge in the interior of the basin. It contains several thin seams of coal, from 6 to 16 inches in thickness. 6. On this repose a series of about 12 fathoms thick, consisting of 3 seams of coal alternating with shale. 7. This is covered with alternate beds of grit and shale, whose aggregate thickness is about 100 fathoms, occupying a tract in the centre of the basin about 4 miles long, and 2 miles broad. The sandstone No. 5 is probably the equivalent of the Pennant in the preceding figure.

The floor, or pavement, immediately under the coal beds is, almost without exception, a grayish slate-clay, which, when made into bricks, strongly resists the fire. This fire-clay varies in thickness from a fraction of an inch to several fathoms. Clay-ironstone is often disseminated through the shale.

The most complete and simplest form of a coal-field is the entire basin-shape, which we find in some instances without a dislocation. A beautiful example of this is to be seen at Blairstone, in the county of Perth, immediately adjoining the western boundary of Clackmannanshire, as represented in fig. 1052, where the outer elliptical line, marked

A, B, C, D, represents the crop, outburst, or baset edge of the lower coal, and the inner elliptical line represents the crop or baset edge of the superior coal. Fig. 1053 is the

longitudinal section of the line *a b*; and *fig.* 1054 the transverse section of the line *c d*. All the accompanying coal strata partake of the same form and parallelism. These basins are generally elliptical, sometimes nearly circular, but are often very eccentric, being much greater in length than in breadth; and frequently one side of the basin on the short diameter has a much greater dip than the other, which circumstance throws the trough or lower part of the basin concavity much nearer to the one side than to the other. From this view of one entire basin, it is evident that the dip of the coal strata belonging to it runs in opposite directions, on the opposite sides, and that all the strata regularly crop out, and meet the alluvial cover in every point of the circumferential space, like the edges of a nest of common basins. The waving line marks the river Devon.

It is from this basin shape that all the other coal-fields are formed, which are segments of a basin produced by slips, dikes, or dislocations of the strata. If the coals (*fig.* 1052) were dislocated by two slips *b c* and *d e*, the slip *b c* throwing the strata down to the east, and the slip *d e* throwing them as much up in the same direction, the outcrops of the coals would be found in the form represented in *fig.* 1055 of which *fig.* 1056 is the section in the line *a n*, and *fig.* 800 the section in the line *c p*.

The chief difficulty in exploring a country in search of coal, or one where coal-fields are known to exist, arises from the great thickness of alluvial and other cover, which completely hides the outcrop or basset edge of the strata, called by miners the *rock-head*; as also the fissures, dikes, and dislocations of the strata, which so entirely change the structure and bearings of coal-fields, and cause often great loss to the mining adventurer. The alluvial cover on the other hand is beneficial, by protecting the seams of the strata from the superficial waters and rains, which would be apt to drown them, if they were naked. In all these figures of coal-basins, the letter *a* indicates coal.

The absolute shape of the coal-fields in Great Britain has been ascertained with surprising precision. To whatever depth a coal-mine is drained of its water, from that depth it is worked, up to the rise of the water-level line, and each miner continues to advance his room or working-place, till his seam of coal meets the alluvial cover of the outcrop, or is cut off by a dislocation of the strata. In this way the miner travels in *sac-*cession over every point of his field, and can portray its basin-shape most minutely.

Fig. 1058 represents a horizontal plan of the Clackmannanshire coal-field, as if the

strata at the outcrop all around were denuded of the alluvial cover. Only two of the concentric beds, or of their edges *a, a*, are represented, to avoid perplexity. It is to be remembered, however, that all the series of attendant strata lie parallel to the above lines. This plan shows the Ochill mountains, with the north coal-fields, of an oblong elliptical shape, the side of the basin next the mountains being precipitous, as if upheaved by the eruptive action of the Ochill mountains; while the south, the east, and the west edges of the basin shelve out at a great distance from the lower part of the concavity or trough, as miners call it. Thus the alternate beds of coal, shale, and sandstone, all nearly concentric in the north coal-field, dip inwards from all sides towards the central area of the trough. The middle coal-field of this district, however, which is formed by the great north slip, is merely the segment of an elliptical basin, where the strata dip in every direction to the middle of the axis marked with the letter *x*; being the deepest part of the segment. The south coal-field, formed by the great south slip, is likewise the segment of another elliptical basin, similar in all respects to the middle coal-field. Beyond the outcrop of the coals and subordinate strata of the south coal-fields, the counter dip of the strata takes place, producing the mantle-shaped form; whence the coal strata in the Dunmore field, in Stirlingshire, lie in a direction contrary to those of the south coal-field of Clackmannanshire. *o*, are the Ochill mountains.

Fig. 1059 is intended to represent an extensive district of country, containing a great coal-basin, divided into numerous subordinate coal-fields by these dislocations. The lines marked *b* are slips, or faults; the broad lines marked *c* denote dikes; the former dislocate the strata, and change their level, while dikes disjoin the strata with a wall, but do not in general affect their elevation. The two parallel lines marked *a*, represent two seams of coal, variously heaved up and down by the faults; whereas the dikes are seen to pass through the strata without altering their relative position. In this manner, partial coal-fields are distributed over a wide area of country, in every direction.

The only exception to this general form of the coal-fields in Great Britain, is the in-

vertical basin shape; but this is rare. A few examples occur in some districts of England, and in the county of Fife; but even in extensive coal-fields, this convex form is but a partial occurrence, or a deviation by local violence from the ordinary basin. Fig. 1060 is an instance of a convex coal-field exhibited in Staffordshire, at the Castle-

hill, close to the town of Dudley. 1, 1, are limestone strata; 2, 2, are coal. Through this hill, canals have been cut, for working the immense beds of carboniferous limestone. These occur in the lower series of the strata of the coal-field, and therefore at a distance of many miles from the Castle-hill, beyond the outcrop of all the workable coals in the proper basin-shaped part of the field; but by this apparently inverted basin-form, these limestone beds are elevated far above the level of the general surface of the country, and consequently above the level of all the coals. We must regard this seeming inversion as resulting from the approximation of two coal-basins, separated by the baset edges of their mountain limestone repository.

Fig. 1061 is a vertical section of the Dudley coal-basin, the upper coal-bed of which has the astonishing thickness of 30 feet; and this mass extends 7 miles in length, and 4 in breadth. Coal-seams 5 or 6 feet thick, are called *thin* in that district.

Fig. 1062 is a very interesting section of the main coal-basin of Clackmannanshire, as given by Mr. Bald in the Wernerian Society's Memoirs, vol. iii. Here we see it broken into three sub-

ordinate coal-fields, formed by two great faults or dislocations of the strata; but independently of these fractures across the whole series, the strata continue quite regular in their respective alternations, and preserve nearly unchanged their angle of inclination to the horizon. The section shows the south

coal-field dipping northerly, till it is cut across by the great south slip *x*, which dislocates the coal and the parallel strata to the enormous extent of 1230 feet, by which all the coals have been thrown up, not simply to the day, but are not found again till we advance nearly a mile northward, on the line of the dip, where the identical seams of coal, shale, &c. are observed once more with their regular inclination. These coals of the middle area, dip regularly northward till interrupted by the great north slip *y*, which dislocates the strata, and throws them up 700 feet; that is to say, a line prolonged in the direction of any one well-known seam, will run 700 feet above the line of the same seam as it emerges after the middle slip. Immediately adjoining the north slip, the coals and coal-field resume their course, and dip regularly northward, running through a longer range than either of the other two members of the basin, till they arrive at the valley of the Devon, at the foot of the Ochill mountains, where they form a concave curvature, or trough, *a*, and thence rise rapidly in an almost vertical direction at *b*. Here the coals,

with all their associate strata, assume conformity and parallelism with the face of the sienitic-greenstone strata of the Ochill mountains *c*; being raised to the high angle of 73 degrees with the horizon. The coal-seams thus upheaved, are called *edge-metals* by the miners.

In this remarkable coal-field, which has been accurately explored by pitting and boring to the depth of 703 feet, there are no fewer than 142 beds, or distinct strata of coal, shale, and sandstone, &c., variously alternating, an idea of which may be had by inspecting fig. 1063. Among these are 24 beds of coal, which would constitute an aggregate thickness of 59 feet 4 inches; the thinnest seam of coal being 2 inches, and the thickest 9 feet. The strata of this section contain numerous varieties of sandstone, slate-clay, bituminous shale, indurated clay, or fire-clay, and clay ironstone. Neither trap-rock nor limestone is found in connexion with the workable coals; but an immense bed of greenstone, named Abbey Craig, occurs in the western boundary of Clackmannanshire, under which lie regular strata of slate-clay, sandstone, thin beds of limestone, and large spheroidal masses of clay ironstone, with a mixture of lime.

"With regard to slips in coal-fields," says Mr. Bald, "we find that there is a general law connected with them as to the position of the dislocated strata, which is this:—When a slip is met with in the course of working the mines—if when looking to it, the vertical line of the slip or fissure, it forms an acute angle with the line of the pavement upon which the observer stands, we are certain that the strata are dislocated downwards upon the other side of the fissure. On the contrary, if the angle formed by the two lines above mentioned is obtuse, we are certain that the strata are dislocated or thrown upwards upon the other side of the fissure. When the angle is 90°, or a right angle, it is altogether uncertain whether the dislocation throws up or down on the opposite side of the slip. When dikes intercept the strata, they generally only separate the strata the width of the dike, without any dislocation, either up or down; so that if a coal is intercepted by a dike, it is found again by running a mine directly forward, corresponding to the angle or inclination of the coal with the horizon."—*Wernerian Society's Memoirs*, vol. iii. p. 133.*

The Johnstone coal-field, in Renfrewshire, is both singular and interesting. The upper stratum of rock is a mass of compact greenstone or trap, above 100 feet in thickness, not at all in a conformable position with the coal strata, but overlying; next there are a few fathoms of soft sandstone and slate-clay, alternating, and uncommonly soft. Beneath these beds, there are no fewer than ten seams of coal, lying on each other, with a few divisions of dark indurated clay. These coal-seams have an aggregate thickness of no less than 100 feet; a mass of combustible matter, in the form of coal, unparalleled for its accumulation in so narrow a space. The greater part of this field contains only 5 beds of coal; but at the place where the section shown in fig. 1064 is taken, these five coals seem to have been overlapped or made to slide over each other by violence. This structure is represented in fig. 1065 which is a section of the Quarrelton coal in the Johnstone field, showing the overlapped coal and the double coal, with the thick bed of greenstone, overlying the coal-field.

Before proceeding to examine the modes of working coal, I shall introduce here a description of the two principal species of this mineral.

1. *Cubical coal*.—It is black, shining, compact, moderately hard, but easily frangible. When extracted in the mine, it comes out in rectangular masses, of which the smaller fragments are cubical. The lamellæ (reed of the coal) are always parallel to the bed or plane on which the coal rests; a fact which holds generally with this substance. There are two varieties of cubical coal; the *open-burning* and the *caking*. The latter, however small its fragments may be, is quite available for fuel, in consequence of its agglutinating into a mass at a moderate heat, by the abundance of its bitumen. This kind is the true smithy or forge-coal, because it readily forms itself into a vault round the blast of the bellows, which serves for a cupola in concentrating the heat on objects thrust into the cavity.

The open-burning cubical coals are known by several local names; the rough coal or

* This paper does honor to its author, the eminent coal-viewer of Scotland.

coal, from the large masses in which they may be had, and the cherry coal, from the cheerful blaze with which they spontaneously burn; whereas the caking coals, such as most of the Newcastle qualities, require to be frequently poked in the grate. Its specific gravity varies from 1.25 to 1.4.

2. *Slate or splint coal*.—This is dull-black, very compact, much harder, and more difficultly frangible than the preceding. It is readily fissile, like slate, but powerfully resists the cross fracture, which is conchoidal. Specific gravity from 1.26 to 1.40. In working, it separates in large quadrangular sharp-edged masses. It burns without taking, produces much flame and smoke, unless judiciously supplied with air, and leaves frequently a considerable bulk of white ashes. It is the best fuel for distilleries and all large grates, as it makes an open fire, and does not clog up the bars with glassy scoriae. I found good splint coal of the Glasgow field to have a specific gravity of 1.266, and to consist of—carbon, 70.9; hydrogen, 4.3; oxygen, 24.8.

3. *Cannel coal*.—Color between velvet and grayish-black; lustre resinous; fracture even; fragments trapezoidal; hard as splint coal; spec. grav. 1.23 to 1.28. In working, it is detached in four-sided columnar masses, often breaks conchoidal, like pitch, kindles very readily, and burns with a bright white projective flame, like the wick of a candle, whence its name. It occurs most abundantly in the coal-field of Wigan, in Lancashire, in a bed 4 feet thick; and there is a good deal of it in the Clydesdale coal-field, of which it forms the lowest seam that is worked. It produces very little dust in the mine, and hardly soils the fingers with carbonaceous matter. Cannel coal from Woodhall, near Glasgow, spec. grav. 1.228, consists by my analysis of—carbon, 72.22; hydrogen, 3.93; oxygen, 21.05; with a little azote (about 2.8 in 100 parts.) This coal has been found to afford, in the Scotch gas-works, a very rich-burning gas. The azote is there converted into ammonia, of which a considerable quantity is distilled over into the tar-pit.

4. *Glance coal*.—This species has an iron-black color, with an occasional iridescence, like that of tempered steel; lustre in general splendid, shining, and imperfectly metallic; does not soil; easily frangible; fracture flat conchoidal; fragments sharp-edged. It burns without flame or smell, except when it is sulphureous; and it leaves a white-colored ash. It produces no soot, and seems, indeed, to be merely carbon, or coal deprived of its volatile matter or bitumen, and converted into coke by subterranean calcination, frequently from contact with whin-dikes. Glance coal abounds in Ireland, under the name of Kilkenny coal; in Scotland it is called blind coal, from its burning without flame or smoke; and in Wales, it is the malting or stone coal. It contains from 90 to 97 per cent. of carbon. Specific gravity from 1.3 to 1.5; increasing with the proportion of earthy impurities.

The dislocations and obstructions found in coal-fields, which render the search for coal so difficult, and their mining so laborious and uncertain, are the following:—

1. *Dikes*.
2. *Slips or Faults*.
3. *Hitches*.
4. *Troubles*.

The first three infer dislocation of the strata; the fourth changes in the bed of coal itself.

1. A dike is a wall of extraneous matter, which divides all the beds in a coal-field.

Dikes extend not only in one line of bearing through coal-fields for many miles, but run sometimes in different directions, and have often irregular bendings, but no sharp angular turns. When from a few feet to a few fathoms in thickness, they occur sometimes in numbers within a small area of a coal basin, running in various directions, and even crossing each other. Fig. 1066 represents a ground plan of a coal-field, intersected

with greenstone dikes. A B and C D are two dikes standing parallel to each other; E F and G H are cross or oblique dikes, which divide both the coal strata and the primary dikes A B and C D.

2. *Slips or faults* run in straight lines through coal-measures, and at every angle of incidence to each other.

Fig. 1067 represents a ground plan of a coal-field, with two slips A B and C D in the line of bearing of the planes of the strata, which throw them down to the outcrop. This is the simplest form of a slip. Fig. 1068 exhibits part of a coal-field intersected with slips, like a cracked sheet of ice. Here A B is a dike; while the narrow lines show faults of every kind, producing dislocations varying in amount of slip from a few feet to a great many fathoms. The faults at the points a, a, vanish; and the lines at c denote four small partial slips called *hitches*.

The effects of slips and dikes on the coal strata appear more prominently when viewed in a vertical section, than in a ground plan, where they seem to be merely walls, veins, and lines of demarcation. Fig. 1069 is a vertical section of a coal-field, from dip

to rise, showing three strata of coal *a*, *b*, *c*. *A* *n* represents a dike at right angles to the plane of the coal-beds. This rectangular wall merely separates the coal-measures, affecting their line of rise; but further to the rise, the oblique dike *c* *D* interrupts the coals *a*, *b*, *c*, and not only disjoins them, but throws them and their concomitant strata greatly lower down; but still, with this depression, the strata retain their parallelism and general slope. Nearer to the outcrop, another dike *E*, *F*, interrupts the coals *a*, *b*, *c*, not merely breaking the continuity of the planes, but throwing them moderately up, so as to produce a steeper inclination, as shown in the figure. It sometimes happens that the coals in the compartment *H*, betwixt the dikes *c* and *E*, may lie nearly horizontal. and the effect of the dike *E*, *F*, is then to throw out the coals altogether, leaving no vestige of them in the compartment *K*. "Such," says Mr. Bald, from whom these illustrations are borrowed, "are the most prominent changes in the strata, as to their line of direction, produced by dikes; but of these changes there are various modifications."

The effect of slips on the strata is also represented in the vertical section, fig. 1070 where *a*, *b*, *c* are coals with their associated strata. *A*, *B*, is an intersecting slip, which throws all

the coals of the first compartment much lower, as is observable in the second, No. 2; and from the amount of the slip, it brings in other coal-seams, marked 1, 2, 3, not in the compartment No. 1. *c*, *D*, is a slip producing a similar result, but not of the same magnitude. *E*, *F* represents a slip across the strata, reverse in direction to the former; the effect of which is to throw up the coals, as shown in the area No. 4. Such a slip occasionally brings into play seams seated under those marked *a*, *b*, *c*, as seen at 4, 5, 6; and it may happen that the coal marked 4 lies in the prolongation of a well-known seam, as *c*, in the compartment No. 3, when the case becomes puzzling to the miner. In addition to the above varieties, a number of slips or hitches are often seen near one another, as in the area marked No. 5, where the individual displacements are inconsiderable, but the aggregate dislocation may be great, in reference to the seams of the 6th compartment.

fect in one respect to a general law, which may be thus explained:—Let fig. 1072

The results of dikes and slips on a horizontal portion of a field are exemplified in fig. 1071. Where the coal-measures are horizontal, and the faults run at a greater angle than 45° to the line of bearing, they are termed dip and rise faults, as *A* *n*, *c* *D*, *E*, *F*.

Coal-viewers or engineers regard the dislocations now described as being sub-

be a portion of a coal-measure; *A*, being the pavement and *n* the roof of the coal-seam. If, in pursuing the stratum at *c*, a dike *D* occurs, standing at right angles with the pavement, they conclude that the dike is merely a partition-wall between the beds by its own thickness, leaving the coal-seam underanged on either side; but if a dike *F* forms, as at *e*, an obtuse angle with the pavement, they conclude that the dike is not a simple partition between the strata, but has thrown up the several seams into the predicament shown at *o*. Finally, should a dike *H* make at *i* an acute angle with the pavement, they conclude that the dike has thrown down the coal-measures into the position of *k*.

The same important law holds with slips, as I formerly stated; only when they form right angles with the pavement, the case is ambiguous; that is, the strata may be dislocated either upwards or downwards.

Dikes and faults are denominated upthrow or downthrow, according to the position they are met with in working the mine. Thus, in fig. 1069 if the miner in advancing to the rise, the dike *A*, *B* obviously does not change the direction; but *C*, *D* is a downthrow dike of a certain number of fathoms towards the rise of the basin, and *E*, *F* is an upthrow dike likewise towards the rise. On the other hand, when the dikes are met with by the miner in working from the rise to the dip, the names of the above dikes would be reversed; for what is an upthrow in the first case, becomes a downthrow in the second, relative to the mining operations.

3. We have seen that *hitches* are small and partial slips, where the dislocation does not exceed the thickness of the coal-seam; and they are correctly enough called *steps* by the miner. Fig. 1073 represents the operation of the *hitches* *A*, *B*, *C*, *D*, *E*, *F*, *G*, *H*, on the coal-measures. Though observed in

one or two seams of a field, they may not appear in the rest, as is the case with dikes and faults.

4. Troubles in coal-fields are of various kinds.

1. *Irregular layers of sandstone*, appearing in the middle of the coal-seam, and gradually increasing in thickness till they separate the coal into two distinct seams, too thin to continue workable.

2. *Nips*, occasioned by the gradual approximation of the roof

and pavement, till not a vestige of coal is left between them; the softer shale disappearing also at the same time. Figs. 1074 and 1075 represent this accident, which is fortunately rare; the first being a vertical, and the second a horizontal view.

3. *Shaken coal*. It resembles the rubbish of an old waste, being a confused heap of coal-dust, mixed with small pieces of cubical coal, so soft that it can frequently be dug with the spade. This shattering is analogous to that observed occasionally in the flint nodules of the chalk formation; and seems like the effect of some electric tremor of the strata.

In searching for coal in any country, its concomitant rocks ought to be looked for, especially the carboniferous or mountain limestone, known by its organic fossils; (see Ure's Geology, p. 175, and corresponding plate of fossils;) likewise the outcrop of the millstone grit, and the newer red sandstone, among some rifts or *façades* of which, seams of coal may be discerned. But no assurance of coal can be had without boring or pitting.

Skill in boring judiciously for coal, distinguishes the genuine miner from the empirical adventurer, who, ignorant of the general structure of coal-basins, expends labor, time, and money at random, and usually to no purpose; missing the proper coal-field, and leading his employer to sink a shaft where no productive seams can be had. A skilful viewer, therefore, should always direct the boring operations, especially in an unexplored country.

The boring rods should be made of the best and most tenacious Swedish iron; in area, about an inch and a quarter square. Each rod is usually 3 feet long, terminating in a male screw at one end, and a female screw at the other. The boring chisels are commonly 18 inches long, and from 2 inches and a half to 3 inches and a quarter at their cutting edge, which must be tipped with good steel. The chisel is screwed to an intermediate 18-inch rod, called the double box-rod, forming together a rod 3 feet long. There are, moreover, three short rods, a foot, 18 inches, and 2 feet long each, which may be screwed, as occasion requires, to the brace-head, to make the height above the

mouth of the bore convenient for the hands of the men in working the rods. Hence the series of rods becomes a scale of measurement for noting the depth of the bore, and keeping a journal of the strata that are perforated. The brace-head rod, also 18 inches long, has two large eyes or rings at its top, set at right angles to each other, through which arms of wood are fixed for the men to lift and turn the rods by, in the boring process.

When the bore is intended to penetrate but a few fathoms, the whole work may be performed directly by the hands; but when the bore is to be of considerable depth, a lofty triangle of wood is set above the bore hole, with a pulley depending at its summit angle, for conducting the rope to the barrel of a windlass or wheel and axle, secured to the ground with heavy stones. The loose end of the rope is connected to the rods by an oval iron ring, called a runner; and by this mechanism they may be raised and let fall in the boring; or the same effect may be more simply produced by substituting for the wheel and axle, a number of ropes attached to the rod rope, each of which may be pulled by a man, as in raising the ram of the pile engine.

In the Newcastle coal district there are professional master-borers, who undertake to search for coal, and furnish an accurate register of the strata perforated. The average price of boring in England or Scotland, where no uncommon difficulties occur, is six shillings for each of the first five fathoms, twice 6 shillings for each of the second five fathoms, thrice 6 shillings for each of the third five fathoms, and so on; hence the series will be—

1st five fathoms	- - - - -	6s. each	- - - - -	£1 10
2d five fathoms	- - - - -	12s. —	- - - - -	3 0
3d five fathoms	- - - - -	18s. —	- - - - -	4 10
4th five fathoms	- - - - -	24s. —	- - - - -	6 0
<hr/>				<hr/>
20 fathoms of bore	- - - - -	- - - - -	- - - - -	£15 0

Thus the price increases equally with the depth and labor of the bore, and the undertaker usually upholds his rods. There are peculiar cases, however, in which the expense greatly exceeds the above rate.

The boring tools are represented in the following figures:—

Fig. 1076.

1. The brace-head.
2. The common rod.
3. The double-box rod; intermediate piece.
4. The common chisel.
5. The indented chisel.
6. Another of the same.
7. The cross-mouthed chisel.
8. The wimble.
9. The sludger, for bringing up the mud.
10. The rounder.
11. The key for supporting the train of rods at the bore-mouth.
12. The key for screwing together and asunder the rods.
13. The top-piece.
14. The beche, for catching the rod when it breaks in the bore.
15. The runner, for taking hold of the top.
16. The tongued chisel.
17. The right-handed worm screw.
18. The left-handed do.
19. The finger grip or catch.

We shall now explain the manner of conducting a series of bores in searching ground for coal.

Fig. 1077 represents a district of country in which a regular survey has proved the existence and general distribution of coal strata, with a dip to the south, as here shown. In this case, a convenient spot should be pitched upon in the north part

of the district, so that the successive bores put down may advance in the line of the

dip. The first bore may therefore be made at No. 1, to the depth of sixty yards. In the progress of this perforation, many diversities and alternations of strata will be probably passed through, as we see in the sections of the strata; each of which, as to quality and thickness, is noted in the journal, and specimens are preserved. This bore is seen to penetrate the strata *d*, *c*, *b*, *a*, without encountering any coal. Now, suppose that the dip of the strata be one yard in ten, the question is, at what distance from bore No. 1, in a south direction, will a second bore of 60 yards strike the first stratum, *d*, of the preceding? The rule obviously is, to multiply the depth of the bore by the dip, that is, 60 by 10, and the product, 600, gives the distance required; for, by the rule of three, if 1 yard of depression corresponds to 10 in horizontal length, 60 yards of depression will correspond to 600 in length. Hence the bores marked 1, 2, 3, 4, and 5, are successively distributed as in the figure, the spot where the first is let down being regarded as the point of level to which the summits of all the succeeding bores are referred. Should the top of No. 2 bore be 10 yards higher or lower than the top of No. 1, allowance must be made for this difference in the operation; and hence a surface level survey is requisite. Sometimes ravines cut down the strata, and advantage should be taken of them, when they are considerable.

In No. 2, a coal is seen to occur near the surface, and another at the bottom of the bore; the latter seam resting on the first stratum *d*, that occurred in bore No. 1; and No. 2 perforation must be continued a little farther, till it has certainly descended to the stratum *d*. Thus these two bores have, together, proved the beds to the depth of 120 yards.

No. 3 bore being placed according to the preceding rule, will pass through two coal-seams near the surface, and after reaching to nearly its depth of 60 yards, it will touch the stratum *h*, which is the upper stratum of bore No. 2; but since a seam of coal was detected in No. 2, under the stratum *h*, the proof is confirmed by running the borer down through that coal. The field has now been probed to the depth of 180 yards. The fourth bore is next proceeded with, till the two coal-seams met in No. 3 have been penetrated; when a depth of 240 yards has been explored. Hence No. 4 bore could not reach the lower stratum *a*, unless it were sunk 240 yards.

The fifth bore (No. 5) being sunk in like manner, a new coal-seam occurs within a few yards of the surface; but after sinking to the depth at which the coal at the top of the fourth bore was found, an entirely different order of strata will occur. In this dilemma, the bore should be pushed 10 or 20 yards deeper than the 60 yards, to ascertain the alternations of the new range of superposition. It may happen that no coals of any value shall be found, as the figure indicates, in consequence of a slip or dislocation of the strata at *a*, which has thrown up all the coals registered in the former borings, to such an extent that the strata *b*, *a*, of the first bore present themselves immediately on perforating the slip, instead of lying at the depth of 300 yards (5×60), as they would have done, had no dislocation intervened. Some coal-fields, indeed, are so intersected with slips as to bewilder the most experienced miner, which will particularly happen when a lower coal is thrown upon one side of a slip, directly opposite to an upper coal situated on the other side of it; so that if the two seams be of the same thickness, erroneous conclusions are almost inevitable.

When a line of bores is to be conducted from the dip of the strata towards their outcrop, they should be placed a few yards nearer each other than the rule prescribes, lest the strata last passed through be overstepped, so that they may disappear from the register, and a valuable coal-seam may thereby escape notice. In fact, each successive bore should be so set down, that the first of the strata perforated should be the last passed through in the preceding bore; as is exemplified by viewing the bores in the retrograde direction, Nos. 4, 3, and 2. But if the bore No. 2 had gone no deeper than *f*, and the bore No. 1 had been as represented, then the stratum *e*, with its immediately subjacent coal, would have been overstepped, since none of the bores would have touched it; and they would have remained unnoticed in the journal, and unknown.

When the line of dip, and consequently the line of bearing which is at right angles to it, are unknown, they are sought for by making three bores in the following position. —Let fig. 1078 be a horizontal diagram, in which the place of a bore, No. 1, is

shown, which reaches a coal-seam at the depth of 50 yards; bore No. 2 may be made at B, 300 yards from the former; and bore No. 3 at C, equidistant from Nos. 1 and 2, so that the bores are sunk at the three angles of an equilateral triangle. If the coal occur in No. 2 at the depth of 30 yards, and in No. 3 of 44 yards, it is manifest that none of the lines A B, B C, or C A, is in the line of level, which for short distances may be taken for the line of bearing, with coal-seams of moderate dip. But since No. 1 is the deepest of the three bores, and No. 3 next in depth, the line A C joining them must be nearer the line of level than either of the lines A B or B C. The question is, therefore, at what distance on the prolonged line B C is the point for sinking a bore which would reach the coal

at the same depth as No. 1, namely, 50 yards. This problem is solved by the following rule of proportion: as 14 yards (the difference of depth between bores 2 and 3) is to 300 yards (the distance between them), so is 20 (the difference of depth betwixt 1 and 2) to a fourth proportion, or $x = 428$ yards, 1 foot, and 8 inches. Now, this distance, measured from No. 2, reaches to the point D on the prolonged line A C, under which point D the coal will be found at a depth of 50 yards, the same as under A. Hence the line A D is the true level line of the coal-field; and a line B F G, drawn at right angles to it, is the true dip-line of the plane which leads to the outcrop. In the present example the dip is 1 yard in $14\frac{1}{2}$; or 1 in $14\frac{1}{2}$, to adopt the judicious language of the miner; or the sine is 1 to a radius of $14\frac{1}{2}$, measured along the line from B to F. By this theorem for finding the lines of dip and level, the most eligible spot in a coal-field for sinking a shaft may be ascertained.

Suppose the distance from B to G in the line of dip to be 455 yards; then, since every $14\frac{1}{2}$ gives a yard of depression, 455 will give 30 yards, which added to 30 yards, the depth of the bore at B, will make 60 yards for the depth of the same coal-seam at G. Since any line drawn at right angles to the line of level A D is the line of dip, so any line drawn parallel to A D is a level line. Hence, if from C the line C E be drawn parallel to B A, the coal-seam at the points E and C will be found in the same horizontal plane, or 44 yards beneath the surface level, over these two points. The point E level with C may also be found by this proportion: as 20 yards (the difference in depth of the bores under B and A) is to 300 yards (the distance between them), so is 14 yards (the difference of depth under B and C) to 210 yards, or the distance from B to E.

As boring for coal is necessarily carried on in a line perpendicular to the horizon, and as coal-seams lie at every angle of inclination to it, the thickness of the seam as given obliquely by the borer, is always greater than the direct thickness of the coal; and hence the length of that line must be multiplied by the cosine of the angle of dip, in order to find the true power of the seam.

Of fitting or winning a coal-field.—In sinking a shaft for working coal, the great obstacle to be encountered is water, particularly in the first opening of a field, which proceeds from the surface of the adjacent country; for every coal-stratum, however deep it may lie in one part of the basin, always rises till it meets the alluvial cover, or crops out, unless it be met by a slip or dike. When the baset-edge of the strata is covered with gravel or sand, any body or stream of water will readily percolate downwards through it, and fill up the porous interstices between the coal-measures, till arrested by the face of a slip, which acts as a valve or flood-gate, and confines the water to one compartment of the basin, which may, however, be of considerable area, and require a great power of drainage.

In reference to water, coal-fields are divided into two kinds: 1. level free coal; 2. coal not level free. In the practice of mining, if a coal-field, or portion of it, is so situated above the surface of the ocean that a level can be carried from that plane till it intersects the coal, all the coal above the plane of intersection is said to be level free; but if a coal-field, though placed above the surface of the ocean, cannot, on account of the expense, be drained by a level or gallery, but by mechanical power, such a coal-field is said to be not level free.

Besides these general levels of drainage, there are subsidiary levels, called off-takes or drifts, which discharge the water of a mine, not at the mouth of the pit, but at some depth beneath the surface, where, from the form of the country, it may be run off level free. From 20 to 30 fathoms off-take is an object of considerable economy in pumping; but even less is often had recourse to; and when judiciously contrived, may serve to intercept much of the crop water, and prevent it from getting down to the dip part of the coal, where it would become a heavy load on a hydraulic engine.

Day levels were an object of primary importance with the early miners, who had not the gigantic pumping power of the steam-engine at their command. Levels ought to be at least 4 feet wide, and from 5 feet and a half to 6 feet high; which is large

enough for carrying off water, and admitting workmen to make repairs and clear out depositions. When a day-level, however, is to serve the double purpose of drainage and an outlet for coals, it should be nearly 5 feet wide, and have its bottom gutter covered over. In other instances a level not only carries off the water from the colliery, but is converted into a canal for bearing boats loaded with coals for the market. Some subterranean canals are nine feet wide, and twelve feet high, with 5 feet depth of water.

If in the progress of driving a level, workable coals are intersected before reaching the seam which is the main object of the mining adventure, an air-pit may be sunk, of such dimension as to serve for raising the coals. These air-pits do not in general exceed 7 feet in diameter; and they ought to be always cylindrical. Fig. 1079 represents a coal-field where the winning is made by a day-level; *a* is the mouth of the gallery on a level with the sea; *b*, *c*, *d*, *e* are intersected coal-seams, to be drained by the gallery. But the coals beneath this level must obviously be drained by pumping. *A* represents a coal-pit sunk on the coal *e*; and if the gallery be pushed

forward, the coal-seams *f*, *g*, and any others which lie in that direction, will also be drained, and then worked by the pit *A*. The chief obstacle to the execution of day-levels, is presented by quicksands in the alluvial cover, near the entrance of the gallery. The best expedient to be adopted amid this difficulty is the following:—Fig. 1080 represents the strata of a coal-field *A*, with the alluvial earth *a*, *b*, containing the bed of quicksand *b*. The lower part, from which the gallery is required to be carried, is shown by the line *n* *d*. But the quicksand makes it impossible to push forward this day-level directly. The pit *a* *c* must therefore be sunk through the quicksand by means of *tubbing* (to be presently described), and when the pit has descended a few yards into the rock, the gallery or drift may then be pushed forward to the point *e*, when the shaft *e* *d* is put down, after it has been ascertained by boring that the rock-head or bottom of the quicksand at *r* is a few yards higher than the mouth of the small pit *a*. During this operation, all the water and mine-stuff are drawn off by the pit *a*; but whenever the shaft *e* *d* is brought into communication with the gallery, the water is allowed to fill it from *c* to *d*, and rise up both shafts till it overflows at the orifice *a*. From the surface of the water in the deep shaft at *c*, a gallery is begun of the common dimensions, and pushed onwards till the coal sought after is intersected. In this way no drainage level is lost. This kind of drainage gallery, in the form of an inverted siphon, is called a drowned or a blind level.

When a coal-basin is so situated that it cannot be rendered level free, the winning must be made by the aid of machinery. The engines at present employed in the drainage of coal-mines are:—

1. The water-wheel, and water-pressure engine.
2. The atmospheric steam-engine of Newcomen.
3. The steam-engine, both atmospheric and double stroke, of Watt.
4. The expansion steam-engine of Woolf.
5. The high-pressure steam-engine without a condenser.

The depth at which the coal is to be won, or to be drained of moisture, regulates the power of the engine to be applied, taking into account the probable quantity of water which may be found, a circumstance which governs the diameter of the working barrels of the pumps. Experience has proved, that in opening collieries, even in new fields, the water may generally be drawn off by pumps of from 10 to 15 inches diameter; excepting where the strata are connected with rivers, sand-beds filled with water, or marsh-lands. As feeders of water from rivers or sand-beds may be hindered from descending coal-pits, the growth proceeding from these sources need not be taken into account; and it is observed, in sinking shafts, that though the influx which cannot be cut off from the mine, may be at first very great, even beyond the power of the engine for a little while, yet as this excessive flow of water is frequently derived from the drainage of fissures, it eventually becomes manageable. An engine working the pumps for 8 or 10 hours out of the 24, is reckoned adequate to the winning of a new colliery, which reaps no advantage from neighboring hydraulic powers. In the course of years, however, many water-logged fissures come to be cut by the workings, and the coal-seams get excavated towards the outcrop, so that a constant increase of water issues, and thus a colliery which has been long in operation, frequently becomes heavily

loaded with water, and requires the action of its hydraulic machinery both night and day.

Of Engine Pits.—In every winning of coal, the shape of the engine-pit deserves much consideration. For shafts of moderate depth, many forms are in use; as circular, oval, square, octagonal, oblong rectangular, and oblong elliptical. In pits of inconsiderable depth, and where the earthy cover is firm and dry, any shape deemed most convenient may be preferred; but in all deep shafts, no shape but the circular should be admitted. Indeed, when a water-run requires to be stopped by tubbing or cribbing, the circular is the only shape which presents a uniform resistance in every point to the equable circumambient pressure. The elliptical form is the next best, when it deviates little from the circle; but even it has almost always given way to a considerable pressure of water. The circular shape has the advantage, moreover, of strengthening the shaft walls, and is less likely to suffer injury than other figures, should any failure of the pillars left in working out the coal cause the shaft to be shaken by subsidence of the strata. The smallest engine-pit should be ten feet in diameter, to admit of the

pumps being placed in the lesser segment, and the coals to be raised in the larger one, as shown in fig. 1801 which is called a double pit. If much work is contemplated in drawing coals, particularly if their masses be large, it would be advantageous to make the pit more than 10 feet wide. When the area of a shaft is to be divided into three compartments, one for the engine pumps, and two for raising coals, as in fig. 1082 which is denominated a triple pit, it should be 12 feet in diameter. If it is to be divided into four compartments, and made a quadrant shaft, as in fig. 1083 with one space for the pumps, and three for ventilation and coal drawing, the total circle should be 15 feet in diameter. These dimensions are, however, governed by local circumstances, and by the proposed daily discharge of coals.

The shaft, as it passes through the earthy cover, should be securely faced with masonry of jointed ashler, having its joints accurately bevelled to the centre of the circle. Specific directions for building the successive masses of masonry, on a series of rings or cribs of oak or elm, are given by Mr. Bald, article *MINE*, *Brewster's Encyclopædia*, p. 336.

When the alluvial cover is a soft mud, recourse must be had to the operation of tubbing. A circular tub, of the requisite diameter, is made of planks from 2 to 3 inches thick, with the joints bevelled by the radius of the shaft, inside of which are cribs of hard wood, placed from 2 to 4 feet asunder, as circumstances may require. These cribs are constructed of the best heart of oak, sawn out of the natural curvature of the wood, adapted to the radius, in segments from 4 to 6 feet long, from 8 to 10 inches in the bed, and 5 or 6 inches thick. The length of the tub is from 9 to 12 feet, if the layer of mud have that thickness; but a succession of such tubs must be set on each other, provided the body of mud be thicker. The first tub must have its lower edge thinned all round, and shod with sharp iron. If the pit be previously secured to a certain depth, the tub is made to pass within the cradling, and is lowered down with tackles till it rests fair among the soft alluvium. It is then loaded with iron weights at top, to cause it to sink down progressively as the mud is removed from its interior. Should a single tub not reach the solid rock (sandstone or basalt), then another of like

1084

construction is set on, and the gravitating force is transferred to the top. Fig. 1084 represents a bed of quicksand resting on a bed of impervious clay, that immediately covers the rock. *a* is the finished shaft; *a a*, the quicksand; *b b*, the excavation necessarily sloping much outwards; *c c*, the lining of masonry; *d d*, the moating or puddle of clay, hard rammed in behind the stone-work, to render the latter water-tight. In this case, the quicksand, being thin in body, has been kept under for a short period, by the hands of many men scooping it rapidly away as it filled in. But the most effectual method of passing through beds of quicksand, is by means of cast-iron cylinders; called, therefore, cast-iron tubbing. When the pit has a small diameter, these tubs are made about 4 feet high, with strong flanges, and bolt holes inside of the cylinder, and a counterfort ring at the neck of the flange, with brackets; the first tub, however, has no flange at its lower edge, but is rounded to facilitate its descent through the mud. Should the pit be of large diameter, then the cylinders must be cast in segments of 3, 4, or more pieces, joined together with inside vertical flanges, well jointed with oakum and white lead. When the sand-bed is thick, eighty feet, for instance, it is customary to divide that length into three sets of cylinders, each thirty feet long, and so sized as to slide within each other, like the eye tubes of a telescope. These cylinders are pressed down by heavy weights, taking care to

keep the lower part always further down than the top of the quicksand, where the men are at work with their shovels, and where the bottom of the pumps hangs for withdrawing the surface water. This is an improvement adopted of late years in the Newcastle district with remarkable success.

The engine pit being secured, the process of sinking through the rock is ready to be commenced, as soon as the divisions of the pit formed of carpentry, called brattices, are made. In common practice, and where great tightness of jointing is not required, for ventilating inflammable air, bars of wood, called buntons, about 6 inches thick, and 9 deep, are fixed in a horizontal position across the pit, at distances from each other of 10, 20, or 30 feet, according to circumstances. Being all ranged in the same vertical plane, deals an inch and a half thick are nailed to them, with their joints perfectly close; one half of the breadth of a buntun being covered by the ends of the deals. In deep pits, where the ventilation is to be conducted through the brattice, the side of the buntuns next the pumps is covered with deals in the same way, and the joints are rendered secure by being calked with oakum. Fillets of wood are also fixed all the way down on each side of the brattice, constituting what is called a double pit.

When a shaft is to have 3 compartments, it requires more care to form the brattice, as none of the buntuns stretch across the whole space, but merely meet near the middle, and join at certain angles with each other. As the buntuns must therefore sustain each other, on the principle of the arch, they are not laid in a horizontal plane, but have a rise from the sides towards the place of junction of 8 or 9 inches, and are bound together by a three-tongued iron strap. Fillets of wood are carried down the whole depth, not merely at the joinings of the brattice with the sides of the pit, but also at their central place of union; while wooden pillars connect the centre of each set of buntuns with those above and below. Thus the carpentry work acquires sufficient strength and stiffness.

In quadrant shafts the buntuns cross each other towards the middle of the pit, and are generally let into each other about an inch, instead of being half-checked. *Fig. 1081* is a double shaft: *A*, the pump pit; *B*, the pit for raising coal. *Fig. 1082* is a triple shaft; in which *A* is the pump compartment; *B* and *C* are coal-pits. *Fig. 1083* is a quadrant shaft: *A*, the pump pit; *B*, pit of ventilation or upcast for the smoke; *C* and *D*, pits for raising coals.

A depth of 75 fathoms is fully the average of engine pits in Great Britain. In practice, it embraces three sets of pumps. Whenever the shaft is sunk so low that the engine is needed to remove the water, the first set of pumps may be let down by the method represented in *fig. 1085*; where *A* is the pump; *a, a*, strong ears through which pass the iron rods connected with the spears *b b*; *c c* are the lashings; *d*, the hoggar pump; *e*, the hoggar; *f f*, the tackles; *g g*, the single pulleys; *h h*, the tackle fold leading to the capstans; and *i*, the pump-spears. By this mechanical arrangement the pumps are sunk in the most gradual manner, and of their own accord, so to speak, as the pit descends. To the arms of the capstans, sledges are fastened with ropes or chains; these sledges are loaded with weights, as counterpoises to the weight of the column of pumps, and when additional pumps are joined in, more weight is laid on the sledges. As the sinking set of pumps is constantly descending, and the point for the delivery of the water above always varying, a pipe of equal diameter with the pumps, and about 11 feet long, but much lighter in the metal, is attached to *e*, and is terminated by a hose of leather, of sufficient length to reach the cistern where the water is delivered. This is called the hoggar-pipe. In sinking, a vast quantity of air enters with the water, at every stroke of the engine; and therefore the lifting stroke should be very slow, and a momentary stop should take place before the returning stroke, to suffer all the air to escape. As the working barrels are generally 9 or 10 feet long, and the full stroke of the engine from 7 to 8 feet, when at regular work, it is customary to diminish the length of stroke, in sinking, to about 6 feet; because, while the pumps are constantly getting lower, the bucket in the working barrel has its working range progressively higher.

The usual length for a set of pumps, is from 25 to 30 fathoms. Whenever this depth is arrived at by the first set, preparations are made for fixing firmly the upper pit-cistern, into which the upper set of pumps is to be placed, and the water of the second set is to be thrown. If a strong bed of sandstone occurs, a scarcement of it is left projecting about 3 feet into the shaft, which is formed in the course of sinking into a strong chin or bracket, to sustain that part of the cistern in which the superior set of pumps stands. A few feet beneath this scarcement the shaft resumes its usual shape.

But although from 20 to 30 fathoms be the common length of a pump-lift, it sometimes becomes necessary to make it much longer, when no place can be found in the

1086 shaft for lodging a cistern, on account of the tubbing. Hence a pump-lift has been occasionally extended to 70 fathoms; which requires extraordinary strength of materials. The best plan for collaring the pumps in the pit, and keeping them steady in a perpendicular line, is to fix a strong buntun of timber under the joints of each pipe; and to attach the pipes firmly to these buntuns by an iron collar, with screws and nuts, as represented in *fig. 1086*.

The water obtained in sinking through the successive strata is, in ordinary cases, conducted down the walls of the shaft; and if the strata are compact, a spiral groove is cut down the sides of the shaft, and when it can hold no more, the water is drawn off in a spout to the nearest pump-cistern; or a perpendicular groove is cut in the side of the shaft, and a square box-pipe either sunk in it, flush with the sides of the pit, or it is covered with deal boards well fitted over the cavity. Similar spiral rings are formed in succession downwards, which collect the trickling streams, and conduct them into the nearest cistern; or rings, made of wood or cast iron, are inserted flush with the sides of the pipe; and the water is led from one ring to another, through perpendicular pipes, until the undermost ring is full, when it delivers its water into the nearest pump-cistern. Keeping the shaft dry is very important to the comfort of the miners, and the durability of the work.

When an engine shaft happens to pass through a great many beds of coal, a gallery a few yards long is driven into each coal-seam, and a bore then put down from one coal to another, so that the water of each may pass down through these bores to the pump-cisterns.

While a deep pit is sinking, a register is kept of every part of the excavations, and each feeder of water is measured daily, to ascertain its rate of discharge, and whether it increases or abates. The mode of measurement, is by noting the time, with a seconds watch, in which a cistern of 40 or 50 gallons gets filled. There are three modes of keeping back or stopping up these feeders; by plank tubbing; iron tubbing; and by plank cribs. Let *fig. 1087* represent the sinking of a shaft through a variety of strata,

having a top cover of sand, with much water resting on the rock summit. Each plane of the coal-measure rises in a certain direction till it meets the alluvial cover. Hence, the pressure of the water at the bottom of the tubbing that rests on the summit of the rock, is as the depth of water in the superficial alluvium; and if a stratum

a affords a great body of water, while the superjacent stratum *b*, and the subjacent *c*, are impervious to water; if the porous bed *a* be 12 feet thick, while no water occurs in the strata passed through from the rock head, until that depth (supposed to be 50 fathoms from the surface of the water in the cover); in this case, the tubbing or cribbing must sustain the sum of the two water pressures, or 62 fathoms; since the stratum *a* meets the alluvial cover at *d*, the fountain head of all the water that occurs in sinking. Thus we perceive, that though no water-feeder of any magnitude should present itself till the shaft had been sunk 100 fathoms; if this water required to be stopped up or tubbed off through the breadth of a stratum only 3 feet thick, the tubbing floodgate would need to have a strength to resist 100 fathoms of water-pressure. For though the water at first oozes merely in discontinuous particles through the open pores of the sands and sandstones, yet it soon fills them up, like a myriad of tubes, which transfer to the bottom the total weight of the hydrostatic column of 100 fathoms; and experience shows, as we have already stated, that whatever water occurs in coal-pits or in mines, generally speaking, proceeds from the surface of the ground. Hence, if the cover be an impervious bed of clay, very little water will be met with among the strata, in comparison of what would be found under sand.

When several fathoms of the strata must be tubbed, in order to stop up the water-flow, the shaft must be widened regularly to admit the kind of tubbing that is to be inserted; the greatest width being needed for plank-tubbing, and the least for iron-tubbing. *Fig. 1088* represents a shaft excavated for plank-tubbing, where *a*, *a*, *a* are the

1088 impervious strata, *b*, *b* the porous beds water-logged, and *c*, *c* the bottom of the excavation, made level and perfectly smooth with mason-chisels. The same precautions are taken in working off the upper part of the excavation *d*, *d*. In this operation, three kinds of cribs are employed; called wedging, spiking, and main cribs. Besides the stout plank for making the tub, a quantity of well-seasoned and clean reeded deal is required for forming the joints; called sheeting deal by the workmen.

This sheeting deal is always applied in pieces laid endwise, with the end of the fibres towards the area of the pit. Since much of the security from water depends on the

tightness of the tub at its jointing with the rock, several plans have been contrived to effect this object; the most approved being represented in *fig. 1089*. To make room for the lower wedging crib, the recess is excavated a few inches wider, as at *e*; and from *b* to *c*, sheeting deals are laid all around the circle, or a thin stratum of oakum is introduced. On this the wedging crib *d* is applied, and neatly jointed in the radius-line of the pit, each segment being drawn exactly to the circle; and at each of its segments sheeting deal is inserted. This wedging crib must be 10 inches in the bed, and 6 inches deep. The vacuity *e*, at the back of the crib, about 2 and a half inches wide, is filled with pieces of dry clean reeded deal, inserted endwise; which is regularly wedged with one set of wedges all round, and then with a second and a third set of wedges, in the same regular style, to keep the crib in a truly circular posture. By this process, well executed, no water can pass downwards by the back of the crib. The next operation is to fix spiking cribs *f*, to the rock, about 10 or 12 feet from the lower crib, according to the length of the planks to be used for the tubs. They must be set fair to the sweep of the shaft, as on them its true circular figure depends. The tubbing deals *k*, must now be fixed. They are 3 inches thick, 6 broad, and planed on all sides, with the joints accurately worked to the proper bevel for the circle of the pit. The main cribs *g*, *g*, are then to be placed as counterforts, for the support and strength of the tubbing. The upper ends of the first set of tub-planks being cut square and level all round, the second spiking crib *l*, is fixed, and another set of tubbing deals put round like the former, having sheeting deal inserted behind the ends of the two sets at *f*. When this is wedged, the cribs *h*, *h*, are placed.

Oak cribbing is made with pieces of the best oak, from 3 to 4 feet long, 10 inches in the bed, and 7 or 8 inches deep.

The third mode of tubbing, by means of iron cylinders cast in segments, is likely henceforth to supersede the wooden tubbing, from the great reduction in the price of iron, and its superior strength and durability. Each segment is adjusted piece to piece in the circular recess of the pit cut out for their reception. The flange for the wedging joint is best turned inwards. In late improvements of this plan, executed by Mr. Buddle, where the pressure amounted to several hundred feet, the segments were 6 feet long, 2 feet broad, and an inch thick, counterforted with ribs or raised work on the back; the lip of the flange was strong, and supported by brackets. These segments of the iron cylinder are set true to the radius of the pit; and every horizontal and perpendicular joint is made tight with a layer of sheeting deal. A wedging crib is fixed at the bottom, and the segments are built up regularly with joints like ashlerwork. This kind of tubbing can be carried to any height, till the water finds an outlet at the surface, or till strata containing water can be tubbed off, as by the modes of tubbing already described. A shaft finished in this manner presents a smooth lining-wall of iron, the flanges being turned towards the outside of the cylinders. In this iron tubbing, no screw bolts are needed for joining the segments together; as they are packed hard within the pit, like the staves of a cask. There is a shaft in the Newcastle district, where 70 fathoms have been executed in this way, under the direction of Mr. Buddle.

When a porous thin bed or parting betwixt two impervious strata gives out much water, or when the fissures of the strata, called cutters, are very leaky, the water can be completely stopped up by the improved process of wedging. The fissure is cut open with chisels, to a width of two, and a depth of seven inches, as represented in *fig. 1090*. The lips being rounded off about an inch and a half, pieces of clean deal are then driven in, whose face projects no further than the contour of the lips; when the whole is firmly wedged, till the water is entirely stopped. By sloping back the edges of the fissures, and wedging back from the face of the stone, it is not liable to burst or crack off in the operation, as took place in the old way, of driving in the wedge directly.

Ventilation of Engine pits.—In ordinary cases, while the sinking of the shaft is going on, the brattice walls produce a circulation, in consequence of the air being slightly lighter in one compartment than in another. If this does not occur, the circulation of air must be produced by artificial means. The most approved contrivance is, to cover the engine compartment of the shaft with deals, leaving apertures for the pump-spears and tackling to pass through, with hatch-doors for the men, and to carry a brick flue at least 3 feet square, in a horizontal direction, from the mouth of that compartment to an adjoining high chimney connected with a furnace, as represented in *fig. 1091*. *a*, *a*, are double doors, for the fireman to supply fuel by; *b*, the mouth of the horizontal flue; *c*, the furnace; *d*, the ash-pit; *e*, the furnace; *f*, the upright chimney for draught, from 50 to 100 feet high, from 8 to 10 feet square at bottom, and tapering upwards to 3 or 4 feet

square inside. Such a furnace and chimney are also needed for ventilating the coal mine through all its underground workings. When a great quantity of gas issues from one place in a pit, it is proper to carry it up in a square wooden pipe, which terminating at some distance above the surface in a helmet-shaped funnel, fitted to turn like a vane, may cause considerable ventilation of itself; or the top of such a pipe may be connected with a small fireplace, which will cause a rapid current up through it, from the pit. The stones and rubbish produced in sinking are drawn up with horse-gins, when the pit is not deep; but in all shafts of considerable depth, a steam engine is used, and the workmen have now more confidence in them, as to personal safety, than in machines impelled by horses.

The great collieries of Newcastle are frequently worked by means of one shaft divided into compartments, which serves as an engine-pit, and coal-pits, and by these the whole ventilation is carried on to an extent and through ramifications altogether astonishing. This system has been adopted on account of the vast expense of a large shaft, often amounting to 60,000*l.* or 80,000*l.*, including the machinery. The British collieries, however, are in general worked by means of an engine-pit, and a series of other pits, sunk at proper distances for the wants of the colliery.

WORKING OF COAL.

A stratum, bed, or seam of coal, is not a solid mass, of uniform texture, nor always of homogeneous quality in burning. It is often divided and intersected, with its concomitant strata, by what are named partings, backs, cutters, reeds, or ends. Besides the chief partings at the roof and pavement of the coal seam, there are subordinate lines of parting in the coal mass, parallel to these, of variable dimensions. These divisions are delineated in *fig. 1092* where *A, B, C, D, E F G D*, represent a portion of a bed of coal,

the parallelogram *A B D C* the parting at the roof, and *E F G D* the parting at the pavement; *a b, b c, d e*, and *e f*, are the subordinate or intermediate partings; *g h, i k, l m*, the backs; *o p, p q, r s, s t, u v*, and *v w*, the cutters. It is thus manifest that a bed of coal, according to the number of these natural divisions, is subdivided into solid figures of various dimensions, and of a cubical or rhomboidal shape.

When the engine-pit is sunk, and the lodgment formed, a mine is then run in the coal to the rise of the field, or a cropping from the engine-pit to the second pit. This mine may be 6 or 8 feet wide, and carried either in a line directly to the pit bottom, or at right angles to the backs or web of the coal, until it is on a line with the pit, where a mine is set off, upon one side, to the pit bottom. This mine or gallery is carried as nearly parallel to the backs as possible, till the pit is gained. *Fig. 1093* represents this mining operation. *A* is the engine-pit. *B*, the second or by-pit. *A C*, the gallery driven at right angles to the backs. *C B*, the gallery set off to the left hand, parallel to the backs. The next step is to drive the drip-head or main-levels from the engine-pit bottom, or from the dip-hand of the backset immediately contiguous to the engine-pit bottom. In this business, the best colliers are always employed, as the object

is to drive the gallery in a truly level direction, independently of all sinkings or risings of the pavement. For coal seams of ordinary thickness, this gallery is usually not more than 6 feet wide; observing to have on the dip side of the gallery a small quantity of water, like that of a gutter, so that it will always be about 4 or 6 inches deep at the forehead upon the dip-wall. When the level is driven correctly, with the proper depth of water, it is said to have dead water at the forehead. In this operation, therefore, the miner pays no regard to the backs or cutters of the coal; but is guided in his line of direction entirely by the water-level, which he must attend to solely, without regard to slips or dislocations of the strata throwing the coal up or down. In the last figure, the coal-field is a portion of a basin; so that if the shape be uniform and unbroken, and if any point be assumed a dipping from the crop, as *p*, the level lines from that point will be parallel to the line of crop, as *p x, p y*, and the levels from any point whatever a-dipping, will be also parallel to these; and hence, were the coal-field an entire elliptical basin, the dip-head levels carried from any point would be elliptical, and parallel to the crop. If, as is more commonly the case, the coal-field be merely a portion of a basin,

formed by a slip of the strata, as represented in *fig. 1094* where *a, a, a*, is the crop, and *A B*, a slip of great magnitude, forming another coal-field on the side *C*, then the crop not only meets the alluvial cover, but is cut off by the slip at *A* and at *B*. Should any point, therefore, be assigned for an engine-pit, the levels from it will proceed in a line parallel to the crop, as *p d, p c*, and the level on both sides of

the engine-pit will be also cut off by the slip A B. In this figure, the part included between the two curve lines, is the breadth or breast of coal-field won by the engine-pit a; what is not included, is termed the under-dip coal, and can be worked only by one or more new workings towards the dip, according to circumstances.

In British practice, there are four different systems of working coal-mines:—

1. Working with pillars and rooms, styled post and stall, where the pillars left bear such proportion to the coal excavated, as is just adequate to the support of the incumbent strata.

2. Working with post and stall, where the pillars are left of an extra size, and stronger than may be requisite for bearing the superior strata, with the intention of removing a considerable portion of each massive pillar, whenever the regular working of post and stall has been finished in the colliery.

3. Working with post and stall, or with comparatively narrow rooms or boards, whereby an uncommonly large proportion of coal is left, with the view of working back towards the pits, whenever the colliery is worked in this manner to the extent of the coal-field, and then taking away every pillar completely, if possible, and allowing the whole superincumbent strata to crush down, creeping very close to the heads of the miners.

4. Working the long way, being the Shropshire method; which leaves no pillars, but takes out all the coal progressively as the workings advance. On this plan, the incumbent strata crush down, creeping very close to the heads of the miners.

The post and stall system is practised with coals of every thickness. The Shropshire method is adopted generally with thin coals; for when the thickness exceeds 6 or 7 feet, this mode has been found impracticable.

The following considerations must be had in view in establishing a coal-mine:—

1. The lowest coal of the winning should be worked in such a manner as not to injure the working or the value of the upper coals of the field; but if this cannot be done, the upper coals should be worked in the first place.

2. The coals must be examined as to texture, hardness, softness, the number and openness of the backs and cutters.

3. The nature of the pavement of the coal seam, particularly as to hardness and softness; and if soft, to what depth it may be so.

4. The nature of the roof of the coal-seam, whether compact, firm, and strong; or weak and liable to fall; as also the nature of the superincumbent strata.

5. The nature of the alluvial cover of the ground, as to water, quicksands, &c.

6. The situation of rivers, lakes, or marshes, particularly if any be near the outcrop of the coal strata.

7. The situation of towns, villages, and mansion-houses, upon a coal-field, as to the chance of their being injured by any particular mode of mining the coal.

Mr. Bald gives the following general rules for determining the best mode of working coal:—

"1. If the coal, pavement, and roof are of ordinary hardness, the pillars and rooms may be proportioned to each other, corresponding to the depth of the superincumbent strata, providing all the coal proposed to be wrought is taken away by the first working, as in the first system; but if the pillars are to be winged afterwards, they must be left of an extra strength, as in the second system.

"2. If the pavement is soft, and the coal and roof strong, pillars of an extra size must be left, to prevent the pillars sinking into the pavement, and producing a creep.

"3. If the coal is very soft, or has numerous open backs and cutters, the pillars must be left of an extra size, otherwise the pressure of the superincumbent strata will make the pillars fly or break off at the backs and cutters, the result of which would be a total destruction of the pillars, termed a crush or sit, in which the roof sinks to the pavement, and closes up the work.

"4. If the roof is very bad, and of a soft texture, pillars of an extra size are required, and the rooms or boards comparatively very narrow.

"In short, keeping in view all the circumstances, it may be stated generally, that when the coal, pavement, and roof are good, any of the systems before mentioned may be pursued in the working; but if they are soft, the plan is to work with rooms of a moderate width, and with pillars of great extra strength, by which the greater part of the coal may be got out at the last of the work, when the miners retreat to the pit bottom, and there finish the workings of a pit."

Fig. 1095 represents the effects of pillars sinking into the pavement, and producing a creep; and fig. 839 exhibits large pillars and a room, with the roof stratum bending down before it falls at a. Thus the roads will be shut up, the air-courses destroyed, and the whole economy of the mining operations deranged.

The proportion of coal worked out, to that left in the pillars, when all the coal intended to be removed is taken out at the first working, varies from

four fifths to two thirds; but as the loss of even one third of the whole area of coal is far too much, the better mode of working suggested in the third system ought to be adopted.

The proportion of a winning to be worked may be thus calculated. Let fig. 1097 be a small portion of the pillars, rooms, and thirlings formed in a coal-field; *a, a*, are two rooms; *b*, the pillars; *c*, the thirlings (or area worked out). Suppose the rooms to be 12 feet wide, the thirlings to be the same, and the pillars 12 feet on each side; adding the face of the pillar to the width of the room, the sum is 24; and also the end of the pillar to the width of the thirling, the sum is likewise 24: then $24 \times 24 = 576$; and the area of the pillar is $12 \times 12 = 144$; and as 576 divided by 144 gives 4 for a quotient, the result is, that one fourth of the coal is left in pillars, and three fourths extracted. Let *d, e, f, g*, be one winning, and *g, e, k, h*, another. By inspecting the figure, we perceive the workings of a coal-field are resolved into quadrangular areas, having a pillar situated in one of the angles.

In forming the pillars and carrying forwards the boards with regularity, especially where the backs and cutters are very distinct and numerous, it is of importance to work the rooms at right angles to the backs, and the thirlings in the direction of the cutters, however oblique these may be to the backs, as the rooms are by this means conducted with the greatest regularity with regard to each other, kept equidistant, and the pillars are strongest under a given area. At the same time, however, it seldom happens that a back or cutter occurs exactly at the place where a pillar is formed; but this is of no consequence, as the shearing or cutting made by the miner ought to be in a line parallel to the backs and cutters. It frequently happens that the dip-head level intersects the cutters in its progress at a very oblique angle. In this case, when rooms and pillars are set off, the face of the pillar and width of the room must be measured off an extra breadth in proportion to the obliquity, as in fig. 1098. By neglect of this rule, much confusion and irregular work are often produced. It is, moreover, proper to make the first set of pillars next the dip-head level much stronger, even where there is no obliquity, in order to protect that level from being injured by any accidental crush of the strata.

We shall now explain the different systems of working: one of the simplest of which is shown in fig. 1099; where *A* represents the engine-pit, *B* the by-pit, *C* the dip-head levels, always carried in advance of the rooms, and *E* the rise or crop gallery, also carried in advance. These galleries not only open out the work for the miners in the coal-bed, but, being in advance, afford sufficient time for any requisite operation, should the mines be obstructed by dikes or hitches. In the example before us, the rooms or boards are worked from the dip to the crop; the leading rooms, or those most in advance, are on each side of the crop gallery *E*; all the other rooms follow in succession, as shown in the figure; consequently, as the rooms advance to the crop, additional rooms are begun

at the dip-head level, towards *C* and *D*. Should the coal work better in a level-course direction, then the level rooms are next the dip-head level, and the other rooms follow in succession. Hence the rooms are carried a cropping in the one case, till the coal is cropped out, or is no longer workable; and in the other, they are extended as far as the extremity of the dip-head level, which is finally cut off, either by a dike or slip, or by the boundary of the coal-field.

When the winnings are so very deep as from 100 to 200 fathoms, the first workings are carried forward with rooms, pillars, and thirlings, but under a different arrangement, on account of the great depth of the superincumbent strata, the enormous expence incident to sinking a pit, and the order and severity of discipline indispensable to the due ventilation of the mines, the preservation of the workmen, and the prosperity of the whole establishment. To the celebrated Mr. Buddle the British nation is under the greatest obligations for devising a new system of working coal-mines, whereby nearly one third of the coals has been rescued from waste and permanent destruction. This system is named panel work; because, instead of carrying on the coal-field winning in one extended area of rooms and pillars, it is divided into quadrangular panels, each panel containing an area of from 8 to 12 acres; and round each panel is left at first a solid wall of coal from 40 to 50 yards thick. Through the panel walls roads and air-courses are driven, in order to work the coal contained within these walls. Thus all the panels are connected together with the shaft, as to roads and ventilation. Each district or

panel has a particular name; so that any circumstance relative to the details of the colliery, casualties as to falls and crushes, ventilation, and the safety of the workmen, can be referred to a specific place.

Fig. 1100 represents a part of a colliery laid out in four panels, according to the improved method. To render it as distinct as possible, the line of the boards is at right

angles with the dip-head level, or level course of the coal. A is the engine-shaft, divided into three compartments, an engine-pit and two coal-pits, like fig. 1082. One of the coal-pits is the down-cast, by which the atmospheric air is drawn down to ventilate the works; the other coal-pit is the up-cast shaft, at whose bottom the furnace for rarefying the air is placed. B C, is the dip-head level; A E, the rise or crop gallery; K, K, the panel walls; F, a, are two panels completed as to the first work; D, is a panel, with the rooms a, a, a, in regular progress to the rise; H, is a panel fully worked out, whence nearly all the coal has been extracted; the loss amounting in general to no more than a tenth, instead of a third, or even a half, by the old method. By this plan of Mr. Buddle's, also, the pillars of a panel may be worked out at any time most suitable for the economy of the mining operation; whereas formerly, though the size of the pillars and general arrangement of the mine were made with the view of taking out ultimately a great proportion of the pillars, yet it frequently happened that, before the workings were pushed to the proposed extent, some part of the mine gave way, and produced a crush; but the most common misfortune was the pillars sinking into the pavement, and deranging the whole economy of the field. Indeed, the crush or creep often overran the whole of the pillars, and was resisted only by the entire body of coal at the wall faces; so that the ventilation was entirely destroyed, the roads leading from the wall faces to the pit-bottom shut up and rendered useless, and the recovery of the colliery by means of new air-courses, new roads, and by opening up the wall faces or rooms, was attended with prodigious expense and danger. Even when the pillars stood well, the old method was attended with other very great inconveniences. If water broke out in any particular spot of the colliery, it was quite impossible to arrest its progress to the engine-pit; and if the ventilation was thereby obstructed, no idea could be formed where the cause might be found, there being instances of no less than 30 miles of air-courses in one colliery. And if from obstructed ventilation an explosion of the fire-damp occurred while many workmen were occupied along the extended wall faces, it was not possible to determine where the disaster had taken place; nor could the viewers and managers know where to bring relief to the forlorn and mutilated survivors.

In Mr. Buddle's system all these evils are guarded against, as far as human science and foresight can go. He makes the pillars very large, and the rooms or boards narrow; the pillars being in general 12 yards broad, and 24 yards long; the boards 4 yards wide, and the walls or thirlings cut through the pillars from one board to another, only 5 feet wide, for the purpose of ventilation. In the figure, the rooms are represented as proceeding from the dip to the crop, and the panel walls act as barriers thrown round the area of the panel, to prevent the weight of the superincumbent strata from over-running the adjoining panels. Again, when the pillars of a panel are to be worked, one range of pillars, as at I (in H), is first attacked; and as the workmen cut away the furthest

pillars, columns of prop-wood are erected betwixt the pavement and the roof, within a few feet of each other (as shown by the dots), till an area of above 100 square yards is cleared of pillars, presenting a body of strata perhaps 130 fathoms thick, suspended clear and without support, except at the line of the surrounding pillars. This operation is termed working the *goaff*. The only use of the prop-wood is to prevent the seam, which forms the ceiling over the workmen's heads, from falling down and killing them by its splintery fragments. Experience has proved, that before proceeding to take away another set of pillars, it is necessary to allow the last-made goaff to fall. The workmen then begin to draw out the props, which is a most hazardous employment. They begin at the more remote props, and knock them down one after another, retreating quickly under the protection of the remaining props. Meanwhile the roof-stratum begins to break by the sides of the pillars, and falls down in immense pieces; while the workmen still persevere, boldly drawing and retreating till every prop is removed. Nay, should any props be so firmly fixed by the top pressure, that they will not give way to the blows of heavy mauls, they are cut through with axes; the workmen making a point of honor to leave not a single prop in the goaff. The miners next proceed to cut away the pillar nearest to the sides of the goaff, setting prop-wood, then drawing it, and retiring as before, until every panel is removed, excepting small portions of pillars which require to be left under dangerous stones to protect the retreat of the workmen. While this operation is going forward, the goaff extending, the superincumbent strata being exposed with out support over a large area, break progressively higher up; and when strong beds of sandstone are thus giving way, the noise of the rending rocks is very peculiar and terrific; at one time loud and sharp, at another hollow and deep.

As the pillars of the panels are taken away, the panel walls are also worked progressively backwards to the pit bottom; so that only a very small proportion of coal is eventually lost. This method is undoubtedly the best for working such coals as those of Newcastle, considering their great depth beneath the surface, their comparative softness, and the profusion of inflammable air. It is evident that the larger the pillars and panel walls are, in the first working, the greater will be the security of the miners, and the greater the certainty of taking out, in the second stage, the largest proportion of coal. This system may be applied to many of the British collieries; and it will produce a vast quantity of coals beyond the post and stall methods, so generally persisted in.

In thus tearing to pieces the massive rocks over his head, the miner displays a determined and cool intrepidity; but his ingenuity is no less to be admired in contriving modes of carrying currents of pure atmospheric air through every turning of his gloomy labyrinth, so as to sweep away the explosive spirit of the mine.

The fourth system of working coal, is called the *long way*, the long-wall, and the Shropshire method. The plan must at first have been extremely hazardous; though now it is so improved as to be reckoned as safe, if not safer, to the workmen, than the other methods, with rooms and pillars.

The object of the Shropshire system, is to begin at the pit-bottom pillars, and to cut away at once every inch of coal progressively forward, and to allow the whole superincumbent strata to crush down behind and over the heads of the workmen. This plan is pursued chiefly with coals that are thin, and is very seldom adopted when the seam is 7 feet thick; from 4 to 5 feet being reckoned the most favorable thickness for proceeding with comfort, amidst ordinary circumstances, as to roof, pavement, &c. When a pit is opened on a coal to be treated by this method, the position of the coals above the lowest seam sunk to, must first be considered; if the coal beds be contiguous, it will be proper to work the upper one first, and the rest in succession downwards; but if they are 8 fathoms or more apart, with strata of strong texture betwixt them, the working of the lower coals in the first place will do no injury to that of the upper coals, except breaking them, perhaps, a little. In many instances, indeed, by this operation on a lower coal, upper coals are rendered more easily worked.

When the operation is commenced by working on the Shropshire plan, the dip-head levels are driven in the usual manner, and very large bottom pillars are formed, as represented in fig. 1101. Along the rise side of the dip-head level, chains of wall, or long pillars, are also made, from 8 to 10 yards in breadth, and only mined through occasionally, for the sake of ventilation, or of forming new roads. In other cases no pillars are left upon the rise side of the level; but, instead of them, buildings of stone are reared, 4 feet broad at the base, and 9 or 10 feet from the dip side of the level. Though the roads are made 9 feet wide at first, they are reduced to half that width after the full pressure of the strata is upon them. When

ever these points are secured, the operation of cutting away the whole body of the coal begins. The place where the coal is removed, is named the *gobb waste*; and gobbin, or gobb-stuff, is stones or rubbish taken away from the coal, pavement, or roof, to fill up that excavation as much as possible, in order to prevent the crush of superincumbent strata from causing heavy falls, or following the workmen too fast in their descent. Coals mined in this manner work most easily according to the way in which the widest backs and cutters are; and therefore, in the Shropshire mode, the walls stand sometimes in one direction, and sometimes in another; the mine always turning out the best coals when the open backs and cutters face the workmen. As roads must be maintained through the crushed strata, the miners in the first place cut away about 15 feet of coal round the pit-bottom pillars, and along the upper sides of the dip-head chain walls; and then, at the distance of 9 or 10 feet, carry regular buildings of stone 3 feet broad, with props set flush with the faces of these, if necessary. As the miners advance, they erect small pillars of roof or pavement stone in regular lines with the wall face, and sometimes with props intermediate.

There are two principal modifications of the Shropshire plan. The first, or the original system, was to open out the wall round the pit-bottom; and, as the wall face extended, to set off main roads and branches, very like the branches of a tree. These roads were so distributed, that between the ends of any two branches there should be a distance of 30 or 40 yards, as might be most convenient. (See fig. 1101.) Each space of coal betwixt the roads is called a wall; and one half of the coals produced from each wall is carried to the one road, and the other half to the other road. This is a great convenience when the roof is bad; and hence a distance of only 20 yards betwixt the roads is in many instances preferred. In fig. 1101 *a* represents the shaft; *n n*, the wall-face; *a*, the dip-head level; *b*, the roads, from 20 to 40 yards asunder; *c*, the *gobb* or waste, with buildings along the sides of the roads; and *d*, the pillars.

The other Shropshire system is represented in fig. 1102 where *a* shows the pit, with the bottom pillars; *b*, the dip-head levels; *c*, the off-break from the level, where no pillars are left; *d*, the off-break, where pillars remain to secure the level. All roads are protected in the sides by stone buildings, if they can be had, laid off 9 feet wide. After the crush settles, the roads generally remain permanently good, and can, in many cases, be travelled through as easily 50 years after they have been made, as at the first. Should

1102

stones not be forthcoming, coals must be substituted, which are built about 20 inches in the base. In this method, the roads are likewise from 20 to 40 yards apart; but instead of ramifying, they are arranged parallel to each other. The miners secure the waste by gobbing; and three rows of props are carried forwards next the wall faces *a*, with pillars of stone or of coal reared betwixt them. This mode has a more regular appearance than the other; though it is not so generally practised.

In the post and stall system, each man has his own room, and performs all the labor of it; but in that of Shropshire, there is a division of labor among the workmen, who are generally divided into three companies. The first set curves or pools the coal along the whole line of walls, laying in or pooling at least 3 feet, and frequently 45 inches, or 5 quarters, as it is called. These men are named *holers*. As the crush is constantly following them, and impending over their heads, causing frequent falls of coal, they plant props of wood for their protection at regular distances in an oblique direction between the pavement and wall face. Indeed, as a further precaution, staples of coal, about 10 inches square, are left at every 6 or 8 yards, till the line of holing or curving is completed. The walls are then marked off into spaces of from 6 to 8 yards in length; and at each space a shearing or vertical cut is made, as deep as the holing; and when this is done, the *holer's* work is finished. The set who succeed the *holers*, are called *getters*. These commence their operations at the centre of the wall divisions, and drive out the *gibbs* and staples. They next set wedges along the roof, and bring down progressively each division of coal; or, if the roof be hard-bound, the coal is blown down with gunpowder. When the roof has a good parting, the coals frequently fall down the moment the *gibbs* are struck; which makes the work very easy. The *getters* are relieved in their turn by the third set, named *butty-men*, who break down the coals into pieces of a proper size for sending up the shaft, and take charge of turning out the coal from the wall face to the ends of the roads. This being done, they build up the stone pillars, fill up the *gobb*, set the trees, clear the wall faces of all obstructions, set the *gibbs*, and make every thing clear and open for the *holers* to resume their work. If the roads are to be heightened by taking down the roof, or removing the pavement, these *butty-men* do this work also, building forwards the sides of the roads, and securing them with the requisite props. When a coal has a following or roof stone, which regularly separates with the coal, this facilitates the labor, and saves much of the coal.

and should a soft bed of fire-clay occur a foot or two beneath the coal-seam, the holing is made in it, instead of into the coal, and the stone betwixt the holing and the coal benched down, which serves for pillars and gobbing. In this way all the vendible coal becomes available.

Another form of the Shropshire system is, for each miner to have from 6 to 12 feet of coal before him, with a leading-hand man; and for the several workmen to follow in succession, like the steps of a stair. When the coal has open backs and cutters, this work goes on very regularly, as represented in *fig. 1103* where the leading miner is at *a* next to the outcrop, and *b b*, &c. are the wall faces of each workman; *A* being the shaft, and *n* the dip-head level. In this case the roads are carried either progressively through the gob, or the gob is entirely shut up; and the whole of the coals are brought down the wall-faces, either to the dip-head level or the road *c, c*. This method may be varied by making the walls broad enough to hold two, three, or four men when each set of miners performs the whole work of holing, getting, breaking down, and carrying off the coals.

B It is estimated that from one eighth to one twelfth part only of the coals remains under ground by the Shropshire plan; nay, in favorable circumstances, almost every inch of coal may be taken out, as its principle is to leave no solid pillars nor any coal below, except what may be indispensable for securing the gob. Indeed, this system might be applied to coal-seams of almost any ordinary thickness, providing stuff to fill up the gob could be conveniently procured.

In Great Britain, seams of coal are mined when they are only 18 inches thick; but if thinner, the working of fire-clay or ironstone immediately adjoining must be included. A few instances may be adduced, indeed, where caking coals of a fine quality for blacksmiths have been worked, though only in 12-inch seams.

Eighteen-inch seams are best worked by young lads and boys. The coal itself may be mined without lifting the pavement, or taking down the roof in the rooms; but roads must be cut either in the pavement or the roof, for removing the coals to the pit-bottom. All coals less than 2 feet 3 inches thick, are worked with the view of taking out all the coal, either on the Shropshire system, or with pillar-walls and rooms; with this peculiarity, that, on account of the thinness of the seam, the rooms are worked as wide as the roof will bear up; or if a following of the roof-stone, or fall of it, can be brought on, it proves advantageous, by not only giving head-room, but by filling up the waste, and rendering the roads easily kept for the working of the pillars. Where no following takes place, small temporary pillars, about 8 feet square, are left along the chain-wall side. The walls may vary in thickness from 4 to 16 yards, according to circumstances, and they are holed through only for ventilation.

Coals from 5 to 8 feet thick are the best suited in every point of view for the effective work of the miner, and for the general economy of underground operations. When they exceed that thickness, they require very excellent roofs and pavements, to render the working either safe or comfortable; or to enable those who superintend the field to get out a fair proportion of coal from a given area. In such powerful beds the Shropshire method is impracticable, from want of gobbin; and long props, unless of prodigious girth, would present an inadequate resistance to the pressure of the massive ceiling.

When coals do not exceed 20 feet in thickness, and have good roofs, they are sometimes worked as one bed of coal; but if the coal be tender or free, it is worked as two beds. One half of such thick coal, however, is in general lost in pillars; and it is very seldom that less than one third can be left. When the coal is free and ready to crumble by the incumbent pressure, as well as by the action of the air, the upper portion of the coal is first worked, then a scaffolding of coal is left, 2 or 3 feet thick, according to the compactness of the coal; and the lower part of the coal is now worked, as shown in

fig. 1104. As soon as the workings are completed to the proposed extent, the coal scaffolding is worked away, and as much of the pillars as can be removed with safety. As propwood is of no use in coal-seams of such a height, and as falls from the roof would prove frequently fatal to the miners, it is customary with tender roofs to leave a ceiling of coal from 2 to 3 feet thick. This makes an excellent roof; and should it break, gives warning beforehand, by a peculiar crackling noise, very different from that of roof-stones crushing down.

One of the thickest coals in Great Britain, worked as one bed from roof to pavement, is the very remarkable seam near the town of Dudley, known by the name of the ten-yard coal, about 7 miles long, and 4 broad. No similar coal has been found in the island; and the mode of working it is quite peculiar, being a species of panel work

totally different from the modern Newcastle system. A compartment, or panel, formed in working the coal, is called a side of work and as the whole operation is exhibited in one of these compartments, it will be proper to describe the mode of taking the coal from one of them, before describing the whole extent of the workings of a mine.

Let *fig. 1105* represent a side of work; *a*, the ribs or walls of coal left standing round, constituting the side of work; *a*, the pillars, 8 yards square; *c*, the stalls, 11 yards wide;

d, the cross-openings, or through puts, also 11 yards wide; *e*, the bolt-hole, cut through the rib from the main road, by which bolt-hole the side of work is opened up, and all the coals removed. Two, three, or even four bolt-holes open into a side of work, according to its extent; they are about 8 feet wide, and 9 feet high. The working is in a great measure regulated by the natural fissures and joints of the coal-seam; and though it is 30 feet thick, the lower band, of 2 feet 3 inches, is worked first; the miners choosing to confine themselves within this narrow opening, in order to gain the greater advantage afterwards, in working the superjacent coal. Whenever the bolt hole is cut through, the work is opened up by driving a gallery forward, 4 feet wide, as shown by the dotted lines. At the sides of this gallery next the bolt-hole, each miner breaks off in succession a breast of coal,

two yards broad, as at *f, f*, by means of which the sides of the rib-walls *A* are formed, and the area of the pillars. In this way each collier follows another, as in one of the systems of the Shropshire plan. When the side of work is laid open along the rib-walls, and the faces and sides of the pillars have been formed, the upper coals are then begun to be worked, next the rib-wall. This is done by shearing up to a bed next the bolt-hole, and on each side, whereby the head coals are brought regularly down in large cubical masses, of such thickness as suits with the free partings or subordinate divisions of the coals and bands. Props of wood, or even stone pillars, are placed at convenient distances for the security of the miners.

In working the ten-yard coal, a very large proportion of it is left under ground, not merely in pillars and rib-walls, but in the state of small coal produced in breaking out the coal. Hence, from four tenths to a half of the total amount is lost for ever.
